The Publishers and the Author will be grateful to any of the readers of this volume who will kindly call their attention to any errors of omission or of commission that they may find therein. It is intended to make our publications standard works of study and reference, and, to that end, the greatest accuracy is sought. It rarely happens that the early editions of works of any size are free from errors; but it is the endeavor of the Publishers to have them removed immediately upon being discovered, and it is therefore desired that the Author may be aided in his task of revision, from time to time, by the kindly criticism of his readers.

# PREFACE.

MORE than twenty years ago the author began to follow the advice given by Nystrom: "Every engineer should make his own pocket-book, as he proceeds in study and practice, to suit his particular business." The manuscript pocket-book thus begun, however, soon gave place to more modern means for disposing of the accumulation of engineering facts and figures, viz., the index rerum, the scrap-book, the collection of indexed envelopes, portfolios and boxes, the card catalogue, etc. Four years ago, at the request of the publishers, the labor was begun of selecting from this accumulated mass such matter as pertained to mechanical engineering, and of condensing, digesting, and arranging it in form for publication. In addition to this, a careful examination was made of the transactions of engineering societies, and of the most important recent works on mechanical engineering, in order to fill gaps that might be left in the original collection, and insure that no important facts had been overlooked.

Some ideas have been kept in mind during the preparation of the Pocket-book that will, it is believed, cause it to differ from other works of its class. In the first place it was considered that the field of mechanical engineering was so great, and the literature of the subject so vast, that as little space as possible should be given to subjects which especially belong to civil engineering. While the mechanical engineer must continually deal with problems which belong properly to civil engineering, this latter branch is so well covered by Trautwine's "Civil Engineer's Pocket-book" that any attempt to treat it exhaustively would not only fill no "long-felt want," but would occupy space which should be given to mechanical engineering.

Another idea prominently kept in view by the author has been that he would not assume the position of an "authority" in giving rules and formulæ for designing, but only that of compiler, giving not only the name of the originator of the rule, where it was known, but also the volume and page from which it was taken, so that its

derivation may be traced when desired. When different formulæ for the same problem have been found they have been given in contrast, and in many cases examples have been calculated by each to show the difference between them. In some cases these differences are quite remarkable, as will be seen under Safety-valves and Crank-pins. Occasionally the study of these differences has led to the author's devising a new formula, in which case the derivation of the formula is given.

Much attention has been paid to the abstracting of data of experiments from recent periodical literature, and numerous references to other data are given. In this respect the present work will be found to differ from other Pocket-books.

The author desires to express his obligation to the many persons who have assisted him in the preparation of the work, to manufacturers who have furnished their catalogues and given permission for the use of their tables, and to many engineers who have contributed original data and tables. The names of these persons are mentioned in their proper places in the text, and in all cases it has been endeavored to give credit to whom credit is due. The thanks of the author are also due to the following gentlemen who have given assistance in revising manuscript or proofs of the sections named: Prof. De Volson Wood, mechanics and turbines; Mr. Frank Richards, compressed air; Mr. Alfred R. Wolff, windmills; Mr. Alex. C. Humphreys, illuminating gas; Mr. Albert E. Mitchell, locomotives; Prof. James E. Denton, refrigerating-machinery; Messrs. Joseph Wetzler and Thomas W. Varley, electrical engineering; and Mr. Walter S. Dix, for valuable contributions on several subjects, and suggestions as to their treatment.

WILLIAM KENT.

PASSAIC, N. J., *April*, 1895.

#### FIFTH EDITION, MARCH, 1900.

Some typographical and other errors discovered in the fourth edition have been corrected. New tables and some additions have been made under the head of Compressed Air. The new (1899) code of the Boiler Test Committee of the American Society of Mechanical Engineers has been substituted for the old (1885) code.

W. K.

# PREFACE TO FOURTH EDITION.

IN this edition many extensive alterations have been made. Much obsolete matter has been cut out and fresh matter substituted. In the first 170 pages but few changes have been found necessary, but a few typographical and other minor errors have been corrected. The tables of sizes, weight, and strength of materials (pages 172 to 282) have been thoroughly revised, many entirely new tables, kindly furnished by manufacturers, having been substituted. Especial attention is called to the new matter on Cast-iron Columns (pages 250 to 253). In the remainder of the book changes of importance have been made in more than 100 pages, and all typographical errors reported to date have been corrected. Manufacturers' tables have been revised by reference to their latest catalogues or from tables furnished by the manufacturers especially for this work. Much new matter is inserted under the heads of Fans and Blowers, Flow of Air in Pipes, and Compressed Air. The chapter on Wire-rope Transmission (pages 917 to 922) has been entirely rewritten. The chapter on Electrical Engineering has been improved by the omission of some matter that has become out of date and the insertion of some new matter.

It has been found necessary to place much of the new matter of this edition in an Appendix, as space could not conveniently be made for it in the body of the book. It has not been found possible to make in the body of the book many of the cross-references which should be made to the items in the Appendix. Users of the book may find it advisable to write in the margin such cross-references as they may desire.

The Index has been thoroughly revised and greatly enlarged.

The author is under continued obligation to many manufacturers who have furnished new tables and data, and to many individual engineers who have furnished new matter, pointed out errors in the earlier editions, and offered helpful suggestions. He will be glad to receive similar aid, which will assist in the further improvement of the book in future editions.

WILLIAM KENT.

PASSAIC, N. J., *September*, 1898.

## SIXTH EDITION. DECEMBER, 1902.

THE chapter on Electrical Engineering has been thoroughly revised, much of the old matter cut out and new matter substituted. Fourteen new pages have been devoted to the subject of Alternating Currents. The chapter on Locomotives has been revised. Some new matter has been added under Cast Iron, Specifications for Steel, Springs, Steam-engines, and Friction and Lubrication. Slight changes and corrections in the text have been made in nearly a hundred pages.

## SEVENTH EDITION, OCTOBER 1904.

AN entirely new index has been made, with about twice as many titles as the former index. The electrical engineering chapter has been further revised and some new matter added. Four pages on Coal Handling Machinery have been inserted at page 911, and numerous minor changes have been made.

W. K.

SYRACUSE, N. Y.

Definitions, Lap, Lead, etc.....	824
Sweet's Valve-diagram.....	826
The Zeuner Valve-diagram.....	827
Port Opening.....	828
Lead.....	829
Inside Lead.....	829
Ratio of Lap and of Port-opening to Valve-travel.....	829
Crank Angles for Connecting-rods of Different Lengths.....	830
Relative Motions of Crosshead and Crank.....	831
Periods of Admission or Cut-off for Various Laps and Travels.....	831
Diagram for Port-opening, Cut-off, and Lap.....	832
Piston-valves.....	834
Setting the Valves of an Engine.....	834
To put an Engine on its Centre.....	834
Link-motion.....	834

**Governors.**

Pendulum or Fly-ball Governors.....	836
To Change the Speed of an Engine.....	837
Fly-wheel or Shaft Governors.....	838
Calculation of Springs for Shaft-governors.....	838

**Condensers, Air-pumps, Circulating-pumps, etc.**

	PAGE
The Jet Condenser. . . . .	839
Ejector Condensers. . . . .	840
The Surface Condenser. . . . .	840
Condenser Tubes. . . . .	840
Tube-plates. . . . .	841
Spacing of Tubes. . . . .	841
Quantity of Cooling Water. . . . .	841
Air-pump. . . . .	841
Area through Valve-seats. . . . .	842
Circulating-pump. . . . .	843
Feed-pumps for Marine Engines . . . . .	843
An Evaporative Surface Condenser. . . . .	844
Continuous Use of Condensing Water. . . . .	844
Increase of Power by Condensers. . . . .	846
Evaporators and Distillers. . . . .	847

**GAS, PETROLEUM, AND HOT-AIR ENGINES.**

Gas-engines. . . . .	847
Efficiency of the Gas-engine. . . . .	848
Tests of the Simplex Gas-engine. . . . .	848
A 320-H.P. Gas-engine. . . . .	848
Test of an Otto Gas-engine. . . . .	849
Temperatures and Pressures Developed. . . . .	849
Test of the Clerk Gas-engine. . . . .	849
Combustion of the Gas in the Otto Engine. . . . .	849
Use of Carburetted Air in Gas-engines. . . . .	849
The Otto Gasoline-engine. . . . .	850
The Priestman Petroleum-engine. . . . .	850
Test of a 5-H.P. Priestman Petroleum-engine . . . . .	850
Naphtha-engines. . . . .	851
Hot-air or Caloric Engines . . . . .	851
Test of a Hot-air Engine . . . . .	851

**LOCOMOTIVES.**

Resistance of Trains. . . . .	851
Inertia and Resistance at Increasing Speeds. . . . .	853
Efficiency of the Mechanism of a Locomotive. . . . .	854
Size of Locomotive Cylinders. . . . .	855
Size of Locomotive Boilers. . . . .	855
Qualities Essential for a Free-steaming Locomotive. . . . .	855
Wootten's Locomotive. . . . .	855
Grate-surface, Smokestacks, and Exhaust-nozzles for Locomotives . . . . .	856
Exhaust Nozzles. . . . .	856
Fire-brick Arches. . . . .	857
Size, Weight, Tractive Power, etc. . . . .	857
Leading American Types. . . . .	858
Steam Distribution for High Speed. . . . .	858
Speed of Railway Trains. . . . .	859
Formulæ for Curves. . . . .	859a
Performance of a High-speed Locomotive. . . . .	859a
Locomotive Link-motion. . . . .	859a
Dimensions of Some American Locomotives. . . . .	859-862
Indicated Water Consumption. . . . .	862
Locomotive Testing Apparatus. . . . .	863
Waste of Fuel in Locomotives. . . . .	863
Advantages of Compounding. . . . .	863
Counterbalancing Locomotives. . . . .	864
Maximum Safe Load on Steel Rails. . . . .	865
Narrow-gauge Railways. . . . .	865
Petroleum-burning Locomotives. . . . .	865
Fireless Locomotives. . . . .	866

**SHAFTING.**

Diameters to Resist Torsional Strain. . . . .	867
Deflection of Shafting. . . . .	868
Horse-power Transmitted by Shafting. . . . .	869
Table for Laying Out Shafting. . . . .	871

**PULLEYS.**

	PAGE
Proportions of Pulleys.....	873
Convexity of Pulleys.....	874
Cone or Step Pulleys.....	874

**BELTING.**

Theory of Belts and Bands.....	876
Centrifugal Tension.....	876
Belting Practice, Formulæ for Belting.....	877
Horse-power of a Belt one inch wide.....	878
A. F. Nagle's Formula.....	878
Width of Belt for Given Horse-power.....	879
Taylor's Rules for Belting.....	880
Notes on Belting.....	882
Lacing of Belts.....	883
Setting a Belt on Quarter-twist.....	883
To Find the Length of Belt.....	884
To Find the Angle of the Arc of Contact.....	884
To Find the Length of Belt when Closely Rolled.....	884
To Find the Approximate Weight of Belts.....	884
Relations of the Size and Speeds of Driving and Driven Pulleys.....	884
Evils of Tight Belts.....	885
Sag of Belts.....	885
Arrangements of Belts and Pulleys.....	885
Care of Belts.....	886
Strength of Belting.....	886
Adhesion, Independent of Diameter.....	886
Endless Belts.....	886
Belt Data.....	886
Belt Dressing.....	887
Cement for Cloth or Leather.....	887
Rubber Belting.....	887

**GEARING.**

Pitch, Pitch-circle, etc.....	887
Diametral and Circular Pitch.....	888
Chordal Pitch.....	889
Diameter of Pitch-line of Wheels from 10 to 100 Teeth.....	889
Proportions of Teeth.....	889
Proportion of Gear-wheels.....	891
Width of Teeth.....	891
Rules for Calculating the Speed of Gears and Pulleys.....	891
Milling Cutters for Interchangeable Gears.....	892

**Forms of the Teeth.**

The Cycloidal Tooth.....	892
The Involute Tooth.....	894
Approximation by Circular Arcs.....	896
Stepped Gears.....	897
Twisted Teeth.....	897
Spiral Gears.....	897
Worm Gearing.....	897
Teeth of Bevel-wheels.....	898
Annular and Differential Gearing.....	898
Efficiency of Gearing.....	899

**Strength of Gear Teeth.**

Various Formulæ for Strength.....	900
Comparison of Formulæ.....	903
Maximum Speed of Gearing.....	905
A Heavy Machine-cut Spur-gear.....	905
Frictional Gearing.....	905
Frictional Grooved Gearing.....	906

**HOISTING.**

Weight and Strength of Cordage.....	906
Working Strength of Blocks.....	906

	PAGE
Efficiency of Chain-blocks. . . . .	907
Proportions of Hooks. . . . .	907
Power of Hoisting Engines. . . . .	908
Effect of Slack Rope on Strain in Hoisting. . . . .	908
Limit of Depth for Hoisting. . . . .	908
Large Hoisting Records. . . . .	908
Pneumatic Hoisting. . . . .	909
Counterbalancing of Winding-engines. . . . .	909

### Cranes.

Classification of Cranes. . . . .	911
Position of the Inclined Brace in a Jib Crane . . . . .	912
A Large Travelling-crane. . . . .	912
A 150-ton Pillar Crane. . . . .	912
Compressed-air Travelling Cranes. . . . .	912

### Coal-handling Machinery.

Weight of Overhead Bins. . . . .	912 <i>a</i>
Supply-pipes from Bins . . . . .	912 <i>a</i>
Types of Coal Elevators. . . . .	912 <i>a</i>
Combined Elevators and Conveyors . . . . .	912 <i>a</i>
Coal Conveyors. . . . .	912 <i>a</i>
Weight of Chain. . . . .	912 <i>b</i>
Weight of Flights . . . . .	912 <i>c</i>
Horse-power of Conveyors. . . . .	912 <i>c</i>
Bucket Conveyors. . . . .	912 <i>c</i>
Screw Conveyors. . . . .	912 <i>d</i>
Belt Conveyors. . . . .	912 <i>d</i>
Capacity of Belt Conveyors. . . . .	912 <i>d</i>

### Wire-rope Haulage.

Self-acting Inclined Plane. . . . .	913
Simple Engine Plane . . . . .	913
Tail-rope System. . . . .	913
Endless Rope System. . . . .	914
Wire-rope Tramways. . . . .	914
Suspension Cableways and Cable Hoists. . . . .	915
Stress in Hoisting-ropes on Inclined Planes. . . . .	915
Tension Required to Prevent Wire Slipping on Drums. . . . .	916
Taper Ropes of Uniform Tensile Strength. . . . .	916
Effect of Various Sized Drums on the Life of Wire Ropes. . . . .	917

### WIRE-ROPE TRANSMISSION.

Elastic Limit of Wire Ropes. . . . .	917
Bending Stresses of Wire Ropes. . . . .	918
Horse-power Transmitted. . . . .	919
Diameters of Minimum Sheaves. . . . .	919
Deflections of the Rope. . . . .	920
Long-distance Transmission. . . . .	921

### ROPE DRIVING.

Formulae for Rope Driving. . . . .	922
Horse-power of Transmission at Various Speeds. . . . .	924
Sag of the Rope Between Pulleys. . . . .	925
Tension on the Slack Part of the Rope. . . . .	925
Miscellaneous Notes on Rope-driving. . . . .	926

### FRICTION AND LUBRICATION.

Coefficient of Friction. . . . .	928
Rolling Friction. . . . .	928
Friction of Solids. . . . .	928
Friction of Rest. . . . .	928
Laws of Unlubricated Friction. . . . .	928
Friction of Sliding Steel Tires. . . . .	928
Coefficient of Rolling Friction. . . . .	929
Laws of Fluid Friction. . . . .	929
Angles of Repose. . . . .	929

	PAGE
Friction of Motion. . . . .	929
Coefficient of Friction of Journal. . . . .	930
Experiments on Friction of a Journal. . . . .	931
Coefficients of Friction of Journal with Oil Bath. . . . .	932
Coefficients of Friction of Motion and of Rest. . . . .	932
Value of Anti-friction Metals. . . . .	932
Cast-iron for Bearings. . . . .	933
Friction of Metal Under Steam-pressure . . . . .	933
Morin's Laws of Friction . . . . .	933
Laws of Friction of well-lubricated Journals. . . . .	934
Allowable Pressures on Bearing-surface. . . . .	935
Oil-pressure in a Bearing. . . . .	937
Friction of Car-journal Brasses. . . . .	937
Experiments on Overheating of Bearings. . . . .	938
Moment of Friction and Work of Friction . . . . .	938
Pivot Bearings. . . . .	939
The Schiele Curve. . . . .	939
Friction of a Flat Pivot-bearing. . . . .	939
Mercury-bath Pivot. . . . .	940
Ball Bearings. . . . .	940
Friction Rollers. . . . .	940
Bearings for Very High Rotative Speed. . . . .	941
Friction of Steam-engines. . . . .	941
Distribution of the Friction of Engines. . . . .	941

### Lubrication.

Durability of Lubricants. . . . .	942
Qualifications of Lubricants. . . . .	943
Amount of Oil to run an Engine. . . . .	943
Examination of Oils. . . . .	943
Penna. R. R. Specifications. . . . .	944
Soda Mixture for Machine Tools . . . . .	945
Solid Lubricants. . . . .	945
Graphite, Soapstone, Fibre-graphite, Metaline. . . . .	945

### THE FOUNDRY.

Cupola Practice. . . . .	946
Charging a Cupola. . . . .	948
Charges in Stove Foundries. . . . .	949
Results of Increased Driving. . . . .	949
Pressure Blowers. . . . .	950
Loss of Iron in Melting. . . . .	950
Use of Softeners. . . . .	950
Shrinkage of Castings. . . . .	951
Weight of Castings from Weight of Pattern. . . . .	952
Moulding Sand. . . . .	952
Foundry Ladles. . . . .	952

### THE MACHINE SHOP.

Speed of Cutting Tools. . . . .	953
Table of Cutting Speeds. . . . .	954
Speed of Turret Lathes. . . . .	954
Forms of Cutting Tools. . . . .	955
Rule for Gearing Lathes. . . . .	955
Change-gears for Lathes. . . . .	956
Metric Screw-threads. . . . .	956
Setting the Taper in a Lathe. . . . .	956
Speed of Drilling Holes. . . . .	956
Speed of Twist-drills. . . . .	957
Milling Cutters. . . . .	957
Speed of Cutters. . . . .	958
Results with Milling-machines. . . . .	959
Milling with or Against Feed. . . . .	960
Milling-machine vs. Planer. . . . .	960
Power Required for Machine Tools. . . . .	960
Heavy Work on a Planer. . . . .	960
Horse-power to run Lathes. . . . .	961

	PAGE
Power used by Machine Tools . . . . .	963
Power Required to Drive Machinery. . . . .	964
Power used in Machine-shops. . . . .	965

### Abrasive Processes.

The Cold Saw. . . . .	966
Reese's Fusing-disk. . . . .	966
Cutting Stone with Wire. . . . .	966
The Sand-blast. . . . .	966
Emery-wheels. . . . .	967-969
Grindstones. . . . .	968-970

### Various Tools and Processes.

Taps for Machine-screws. . . . .	970
Tap Drills. . . . .	971
Taper Bolts, Pins, Reamers, etc. . . . .	972
Punches, Dies, Presses. . . . .	972
Clearance Between Punch and Die. . . . .	972
Size of Blanks for Drawing-press. . . . .	973
Pressure of Drop-press. . . . .	973
Flow of Metals. . . . .	973
Forcing and Shrinking Fits. . . . .	973
Efficiency of Screws. . . . .	974
Powell's Screw-thread. . . . .	975
Proportioning Parts of Machine. . . . .	975
Keys for Gearing, etc. . . . .	975
Holding-power of Set-screws. . . . .	977
Holding-power of Keys. . . . .	978

### DYNAMOMETERS.

Traction Dynamometers. . . . .	978
The Prony Brake. . . . .	978
The Alden Dynamometer. . . . .	979
Capacity of Friction-brakes. . . . .	980
Transmission Dynamometers. . . . .	980

### ICE MAKING OR REFRIGERATING MACHINES.

Operations of a Refrigerator-machine. . . . .	981
Pressures, etc., of Available Liquids. . . . .	982
Ice-melting Effect. . . . .	983
Ether-machines. . . . .	983
Air-machines. . . . .	983
Ammonia Compression-machines. . . . .	983
Ammonia Absorption-machines. . . . .	984
Sulphur-dioxide Machines. . . . .	985
Performance of Ammonia Compression-machines. . . . .	986
Economy of Ammonia Compression-machines. . . . .	987
Machines Using Vapor of Water. . . . .	988
Efficiency of a Refrigerating-machine. . . . .	988
Test Trials of Refrigerating-machines. . . . .	990
Temperature Range. . . . .	991
Metering the Ammonia . . . . .	992
Properties of Sulphur Dioxide and Ammonia Gas. . . . .	992
Properties of Brine used to absorb Refrigerating Effect. . . . .	994
Chloride-of-calcium Solution. . . . .	994

### Actual Performances of Refrigerating Machines.

Performance of a 75-ton Refrigerating-machine. . . . .	994, 998
Cylinder-heating. . . . .	997
Tests of Ammonia Absorption-machine. . . . .	997
Ammonia Compression-machine, Results of Tests. . . . .	999
Means for Applying the Cold. . . . .	999

### Artificial Ice-manufacture.

Test of the New York Hygeia Ice-making Plant. . . . .	1000
---	------

**MARINE ENGINEERING.**

	PAGE
Rules for Measuring Dimensions and Obtaining Tonnage of Vessels. . .	1001
The Displacement of a Vessel. . . . .	1001
Coefficient of Fineness. . . . .	1002
Coefficient of Water-lines. . . . .	1002
Resistance of Ships. . . . .	1002
Coefficient of Performance of Vessels. . . . .	1003
Defects of the Common Formula for Resistance. . . . .	1003
Rankine's Formula. . . . .	1003
Dr. Kirk's Method. . . . .	1004
To find the I.H.P. from the Wetted Surface. . . . .	1005
E. R. Mumford's Method. . . . .	1006
Relative Horse-power required for different Speeds of Vessels. . . . .	1006
Resistance per Horse-power for different Speeds. . . . .	1006
Results of Trials of Steam-vessels of Various Sizes. . . . .	1007
Speed on Canals. . . . .	1008
Results of Progressive Speed-trials in Typical Vessels. . . . .	1008
Estimated Displacement, Horse-power, etc., of Steam-vessels of Various Sizes. . . . .	1009

**The Screw-propeller.**

Size of Screw. . . . .	1010
Propeller Coefficients. . . . .	1011
Efficiency of the Propeller. . . . .	1012
Pitch-ratio and Slip for Screws of Standard Form. . . . .	1012
Results of Recent Researches. . . . .	1013

**The Paddle-wheel.**

Paddle-wheel with Radial Floats. . . . .	1013
Feathering Paddle-wheels. . . . .	1013
Efficiency of Paddle-wheels. . . . .	1014

**Jet-propulsion.**

Reaction of a Jet. . . . .	1015
----------------------------	------

**Recent Practice in Marine Engines.**

Forced Draught. . . . .	1015
Boilers. . . . .	1015
Piston-valves. . . . .	1016
Steam-pipes. . . . .	1016
Auxiliary Supply of Fresh-water Evaporators. . . . .	1016
Weir's Feed-water Heater. . . . .	1016
Passenger Steamers fitted with Twin-screws. . . . .	1017
Comparative Results of Working of Marine-engine, 1872, 1881, and 1891. . . . .	1017
Weight of Three-stage Expansion-engines. . . . .	1017
Particulars of Three-stage Expansion-engines. . . . .	1018

**CONSTRUCTION OF BUILDINGS.**

Walls of Warehouses, Stores, Factories, and Stables. . . . .	1019
Strength of Floors, Roofs, and Supports. . . . .	1019
Columns and Posts. . . . .	1019, 1022
Fireproof Buildings. . . . .	1020
Iron and Steel Columns. . . . .	1020
Lintels, Bearings, and Supports. . . . .	1020
Strains on Girders and Rivets. . . . .	1020
<b>Maximum Load on Floors.</b> . . . .	1021
<b>Strength of Floors.</b> . . . .	1021
Safe Distributed Loads on Southern-pine Beams. . . . .	1023

**ELECTRICAL ENGINEERING.**

C. G. S. System of Physical Measurement. . . . .	1024
Practical Units used in Electrical Calculations. . . . .	1024
Relations of Various Units. . . . .	1025
Equivalent Electrical and Mechanical Units. . . . .	1026
Analogies between Flow of Water and Electricity. . . . .	1027

**Electrical Resistance.**

	PAGE
Laws of Electrical Resistance. . . . .	1027
Electrical Conductivity of Different Metals and Alloys. . . . .	1028
Conductors and Insulators. . . . .	1028
Resistance Varies with Temperature. . . . .	1028
Annealing. . . . .	1029
Standard of Resistance of Copper Wire . . . . .	1029

**Direct Electric Currents.**

Ohm's Law . . . . .	1029
Series and Parallel or Multiple Circuits. . . . .	1030
Resistance of Conductors in Series and Parallel. . . . .	1030
Internal Resistance. . . . .	1031
Electrical, Indicated, and Brake Horse-power. . . . .	1031
Power of the Circuit. . . . .	1031
Heat Generated by a Current. . . . .	1031
Heating of Conductors. . . . .	1032
Fusion of Wires. . . . .	1032
Heating of Coils. . . . .	1032
Allowable Carrying Capacity of Copper Wires. . . . .	1033
Underwriters' Insulation . . . . .	1033
Copper-wire Table. . . . .	1034, 1035

**Electric Transmission, Direct Currents.**

Section of Wire Required for a Given Current. . . . .	1033
Weight of Copper for a Given Power. . . . .	1036
Short-circuiting. . . . .	1036
Economy of Electric Transmission. . . . .	1036
Wire Table for 110, 220, 500, 1000, and 2000 volt Circuits. . . . .	1037
Efficiency of Long-distance Transmission. . . . .	1038
Table of Electrical Horse-powers. . . . .	1039
Cost of Copper for Long-distance Transmission. . . . .	1040
Systems of Electrical Distribution. . . . .	1041

**Electric Lighting.**

Arc Lights. . . . .	1042
Incandescent Lamps. . . . .	1042
Variation in Candle-power and Life. . . . .	1042
Specifications for Lamps . . . . .	1043
Special Lamps. . . . .	1043
Nernst Lamp. . . . .	1043

<b>Electric Welding</b> . . . . .	1044
<b>Electric Heaters</b> . . . . .	1044

**Electric Accumulators or Storage-batteries.**

Description of Storage-batteries. . . . .	1045
Sizes and Weights of Storage-batteries. . . . .	1048
General Rules for Storage-cells. . . . .	1048
<b>Electrolysis</b> . . . . .	1048
<b>Electro-chemical Equivalents</b> . . . . .	1049
Efficiency of a Storage-cell. . . . .	1048

**Electro-magnets.**

Units of Electro-magnetic Measurements. . . . .	1050
Lines of Loops of Force. . . . .	1050
The magnetic Circuit. . . . .	1051
Permeability. . . . .	1052
Tractive or Lifting Force of a Magnet. . . . .	1053
Magnet Windings. . . . .	1053
Determining the Polarity of Electro-magnets. . . . .	1054
Determining the Direction of a Current. . . . .	1054

**Dynamo-electric Machines.**

Kinds of Dynamo-electric Machines as regards Manner of Winding. . . . .	1055
Moving Force of a Dynamo-electric Machine. . . . .	1055
Torque of an Armature. . . . .	1056
Electro-motive Force of the Armature Circuit. . . . .	1056
Strength of the Magnetic Field. . . . .	1057
Dynamo Design. . . . .	1058

**Alternating Currents.**

	PAGE
Maximum, Average, and Effective Values. . . . .	1061
Frequency. . . . .	1061
Inductance, Capacity, Power Factor. . . . .	1062
Reactance, Impedance, Admittance. . . . .	1063
Skin Effect Factors. . . . .	1063
Ohm's Law Applied to Alternating Currents. . . . .	1064
Impedance Polygons. . . . .	1066
Capacity of Conductors. . . . .	1066
Self-inductance of Lines and Circuits. . . . .	1066
Capacity of Conductors. . . . .	1067
Single-phase and Polyphase Currents. . . . .	1068
Measurement of Power in Polyphase Circuits. . . . .	1069
Alternating-current Generators. . . . .	1070
Transformers, Converters, etc. . . . .	1070
Synchronous Motors. . . . .	1071
Induction Motors. . . . .	1072
Calculation of Alternating-current Circuits. . . . .	1072
Weight of Copper Required in Different Systems. . . . .	1074

**Electrical Machinery.**

Direct-current Generators and Motors . . . . .	1074-1076
Alternating-current Generators. . . . .	1077
Induction Motors. . . . .	1077
<b>Symbols Used in Electrical Diagrams</b> . . . . .	1078

**APPENDIX.****Strength of Timber.**

Safe Load on White-oak Beams. . . . .	1079
---------------------------------------	------

**Mathematics.**

Formula for Interpolation. . . . .	1080
Maxima and Minima without the Calculus. . . . .	1080

**Riveted Joints.**

Pressure Required to Drive Hot Rivets. . . . .	1080
--	------

**Heating and Ventilation.**

Capacities for Hot-blast or Plenum Heating with Fans and Blowers. . . . .	1081
---	------

**Water-wheels.**

Water-power Plants Operating under High Pressure. . . . .	1081
Formulæ for Power of Jet Water-wheels. . . . .	1082

**Gas Fuel.**

Composition Energy, etc., of Various Gases. . . . .	1082

## Arithmetical and Algebraical Signs and Abbreviations.

+ plus (addition).  
 + positive.  
 - minus (subtraction).  
 - negative.  
 $\pm$  plus or minus.  
 $\mp$  minus or plus.  
 = equals.  
 $\times$  multiplied by.  
 $ab$  or  $a.b = a \times b$ .  
 $\div$  divided by  
 $/$  divided by.  
 $\frac{a}{b} = a/b = a \div b$ .    15-16 =  $\frac{15}{16}$ .  
 $.2 = \frac{2}{10}$ ;  $.002 = \frac{2}{1000}$ .  
 $\sqrt{\quad}$  square root.  
 $\sqrt[3]{\quad}$  cube root.  
 $\sqrt[4]{\quad}$  4th root.  
 : is to, :: so is, : to (proportion).  
 2 : 4 :: 3 : 6, as 2 is to 4 so is 3 to 6.  
 : ratio; divided by.  
 2 : 4, ratio of 2 to 4 = 2/4.  
 $\therefore$  therefore.  
 $>$  greater than.  
 $<$  less than.  
 $\square$  square.  
 $\circ$  round.  
 $^{\circ}$  degrees, arc or thermometer.  
 $'$  minutes or feet.  
 $''$  seconds or inches.  
 $'''$  accents to distinguish letters, as  $a'$ ,  $a''$ ,  $a'''$ .  
 $a_1, a_2, a_3, a_b, a_c$ , read  $a$  sub 1,  $a$  sub  $b$ , etc.  
 ( ) [ ] { } ——— vincula, denoting that the numbers enclosed are to be taken together; as,  
 $(a + b)c = 4 + 3 \times 5 = 35$ .  
 $a^2, a^3$ ,  $a$  squared,  $a$  cubed.  
 $a^n$ ,  $a$  raised to the  $n$ th power.  
 $a^{\frac{2}{3}} = \sqrt[3]{a^2}$ ,  $a^{\frac{3}{2}} = \sqrt{a^3}$ .  
 $a^{-1} = \frac{1}{a}$ ,  $a^{-2} = \frac{1}{a^2}$ .  
 $10^9 = 10$  to the 9th power = 1,000,000,000.  
 $\sin. a$  = the sine of  $a$ .  
 $\sin.^{-1} a$  = the arc whose sine is  $a$ .  
 $\sin. a^{-1} = \frac{1}{\sin. a}$ .  
 $\log.$  = logarithm.  
 $\log_e$  or hyp.  $\log.$  = hyperbolic logarithm.

$\angle$  angle.  
 $\perp$  right angle.  
 $\perp$  perpendicular to.  
 $\sin.$ , sine.  
 $\cos.$ , cosine.  
 $\text{tang.}$ , or  $\text{tan.}$ , tangent.  
 $\text{sec.}$ , secant.  
 $\text{versin.}$ , versed sine.  
 $\text{cot.}$ , cotangent.  
 $\text{cosec.}$ , cosecant.  
 $\text{covers.}$ , co-versed sine.  
 In Algebra, the first letters of the alphabet,  $a, b, c, d$ , etc., are generally used to denote known quantities, and the last letters,  $w, x, y, z$ , etc., unknown quantities.

### *Abbreviations and Symbols commonly used.*

$d$ , differential (in calculus).  
 $\int$ , integral (in calculus).  
 $\int_a^b$ , integral between limits  $a$  and  $b$ .  
 $\Delta$ , delta, difference.  
 $\Sigma$ , sigma, sign of summation.  
 $\pi$ , pi, ratio of circumference of circle to diameter = 3.14159.  
 $g$ , acceleration due to gravity = 32.16 ft. per sec.

### *Abbreviations frequently used in this Book.*

$L.$ ,  $l.$ , length in feet and inches.  
 $B.$ ,  $b.$ , breadth in feet and inches.  
 $D.$ ,  $d.$ , depth or diameter.  
 $H.$ ,  $h.$ , height, feet and inches.  
 $T.$ ,  $t.$ , thickness or temperature.  
 $V.$ ,  $v.$ , velocity.  
 $F.$ , force, or factor of safety.  
 $f.$ , coefficient of friction.  
 $E.$ , coefficient of elasticity.  
 $R.$ ,  $r.$ , radius.  
 $W.$ ,  $w.$ , weight.  
 $P.$ ,  $p.$ , pressure or load.  
 $H.P.$ , horse-power.  
 $I.H.P.$ , indicated horse-power.  
 $B.H.P.$ , brake horse-power.  
 $h. p.$ , high pressure.  
 $i. p.$ , intermediate pressure.  
 $l. p.$ , low pressure.  
 $A.W.G.$ , American Wire Gauge (Brown & Sharpe).  
 $B.W.G.$ , Birmingham Wire Gauge.  
 $r. p. m.$ , or revs. per min., revolutions per minute.

## ARITHMETIC.

The user of this book is supposed to have had a training in arithmetic as well as in elementary algebra. Only those rules are given here which are apt to be easily forgotten.

**GREATEST COMMON MEASURE, OR GREATEST COMMON DIVISOR OF TWO NUMBERS.**

**Rule.**—Divide the greater number by the less; then divide the divisor by the remainder, and so on, dividing always the last divisor by the last remainder, until there is no remainder, and the last divisor is the greatest common measure required.

**LEAST COMMON MULTIPLE OF TWO OR MORE NUMBERS.**

**Rule.**—Divide the given numbers by any number that will divide the greatest number of them without a remainder, and set the quotients with the undivided numbers in a line beneath.

Divide the second line as before, and so on, until there are no two numbers that can be divided; then the continued product of the divisors and last quotients will give the multiple required.

## FRACTIONS.

**To reduce a common fraction to its lowest terms.**—Divide both terms by their greatest common divisor.  $\frac{39}{52} = \frac{3}{4}$ .

**To change an improper fraction to a mixed number.**—Divide the numerator by the denominator; the quotient is the whole number, and the remainder placed over the denominator is the fraction:  $\frac{39}{4} = 9\frac{3}{4}$ .

**To change a mixed number to an improper fraction.**—Multiply the whole number by the denominator of the fraction; to the product add the numerator; place the sum over the denominator:  $1\frac{7}{8} = \frac{15}{8}$ .

**To express a whole number in the form of a fraction with a given denominator.**—Multiply the whole number by the given denominator, and place the product over that denominator:  $13 = \frac{39}{3}$ .

**To reduce a compound to a simple fraction, also to multiply fractions.**—Multiply the numerators together for a new numerator and the denominators together for a new denominator:

$$\frac{2}{3} \text{ of } \frac{4}{3} = \frac{8}{9}, \text{ also } \frac{2}{3} \times \frac{4}{3} = \frac{8}{9}.$$

**To reduce a complex to a simple fraction.**—The numerator and denominator must each first be given the form of a simple fraction; then multiply the numerator of the upper fraction by the denominator of the lower for the new numerator, and the denominator of the upper by the numerator of the lower for the new denominator:

$$\frac{\frac{7}{8}}{1\frac{3}{4}} = \frac{\frac{7}{8}}{\frac{7}{4}} = \frac{28}{56} = \frac{1}{2}.$$

**To divide fractions.**—Reduce both to the form of simple fractions, invert the divisor, and proceed as in multiplication:

$$\frac{3}{4} \div 1\frac{1}{4} = \frac{3}{4} \div \frac{5}{4} = \frac{3}{4} \times \frac{4}{5} = \frac{12}{20} = \frac{3}{5}.$$

**Cancellation of fractions.**—In compound or multiplied fractions, divide any numerator and any denominator by any number which will divide them both without remainder, striking out the numbers thus divided and setting down the quotients in their stead.

**To reduce fractions to a common denominator.**—Reduce each fraction to the form of a simple fraction; then multiply each numera-

tor by all the denominators except its own for the new numerators, and all the denominators together for the common denominator:

$$\frac{1}{2}, \frac{1}{3}, \frac{3}{7} = \frac{21}{42}, \frac{14}{42}, \frac{18}{42}$$

**To add fractions.**—Reduce them to a common denominator, then add the numerators and place their sum over the common denominator:

$$\frac{1}{2} + \frac{1}{3} + \frac{3}{7} = \frac{21 + 14 + 18}{42} = \frac{53}{42} = 1\frac{11}{42}$$

**To subtract fractions.**—Reduce them to a common denominator, subtract the numerators and place the difference over the common denominator:

$$\frac{1}{2} - \frac{3}{7} = \frac{7 - 6}{14} = \frac{1}{14}$$

### DECIMALS.

**To add decimals.**—Set down the figures so that the decimal points are one above the other, then proceed as in simple addition:  $18.75 + .012 = 18.762$ .

**To subtract decimals.**—Set down the figures so that the decimal points are one above the other, then proceed as in simple subtraction:  $18.75 - .012 = 18.738$ .

**To multiply decimals.**—Multiply as in multiplication of whole numbers, then point off as many decimal places as there are in multiplier and multiplicand taken together:  $1.5 \times .02 = .030 = .03$ .

**To divide decimals.**—Divide as in whole numbers, and point off in the quotient as many decimal places as those in the dividend exceed those in the divisor. Ciphers must be added to the dividend to make its decimal places at least equal those in the divisor, and as many more as it is desired to have in the quotient:  $1.5 \div .25 = 6$ .  $0.1 \div 0.3 = 0.10000 \div 0.3 = 0.3333 +$

### Decimal Equivalents of Fractions of One Inch.

**To convert a common fraction into a decimal.**—Divide the numerator by the denominator, adding to the numerator as many ciphers prefixed by a decimal point as are necessary to give the number of decimal places desired in the result:  $\frac{1}{3} = 1.0000 \div 3 = 0.3333 +$ .

**To convert a decimal into a common fraction.**—Set down the decimal as a numerator, and place as the denominator 1 with as many ciphers annexed as there are decimal places in the numerator; erase the

1	1.0000	.0625	.1250	.1875	.2500	.3125	.3750	.4375	.5000	.5625	.6250	.6875	.7500	.8125	.8750	.9375	1.0000

decimal point in the numerator, and reduce the fraction thus formed to its lowest terms:

$$.25 = \frac{25}{100} = \frac{1}{4}; \quad .3333 = \frac{3333}{10000} = \frac{1}{3}, \text{ nearly.}$$

**To reduce a recurring decimal to a common fraction.**—Subtract the decimal figures that do not recur from the whole decimal including one set of recurring figures; set down the remainder as the numerator of the fraction, and as many nines as there are recurring figures, followed by as many ciphers as there are non-recurring figures, in the denominator. Thus:

Subtract  $.79054054$ , the recurring figures being 054.

$$\frac{78975}{99900} = (\text{reduced to its lowest terms}) \frac{117}{148}.$$

### COMPOUND OR DENOMINATE NUMBERS.

**Reduction descending.**—To reduce a compound number to a lower denomination. Multiply the number by as many units of the lower denomination as makes one of the higher.

$$3 \text{ yards to inches: } 3 \times 36 = 108 \text{ inches.}$$

$$.04 \text{ square feet to square inches: } .04 \times 144 = 5.76 \text{ sq. in.}$$

If the given number is in more than one denomination proceed in steps from the highest denomination to the next lower, and so on to the lowest, adding in the units of each denomination as the operation proceeds.

$$3 \text{ yds. } 1 \text{ ft. } 7 \text{ in. to inches: } 3 \times 3 = 9, + 1 = 10, 10 \times 12 = 120, + 7 = 127 \text{ in.}$$

**Reduction ascending.**—To express a number of a lower denomination in terms of a higher, divide the number by the number of units of the lower denomination contained in one of the next higher; the quotient is in the higher denomination, and the remainder, if any, in the lower.

127 inches to higher denomination.

$$127 \div 12 = 10 \text{ feet } + 7 \text{ inches; } 10 \text{ feet } \div 3 = 3 \text{ yards } + 1 \text{ foot.}$$

Ans. 3 yds. 1 ft. 7 in.

To express the result in decimals of the higher denomination, divide the given number by the number of units of the given denomination contained in one of the required denomination, carrying the result to as many places of decimals as may be desired.

$$127 \text{ inches to yards: } 127 \div 36 = 3\frac{5}{18} = 3.5277 + \text{ yards.}$$

### RATIO AND PROPORTION.

**Ratio** is the relation of one number to another, as obtained by dividing one by the other.

$$\text{Ratio of 2 to 4, or } 2 : 4 = 2/4 = 1/2.$$

$$\text{Ratio of 4 to 2, or } 4 : 2 = 2.$$

**Proportion** is the equality of two ratios. Ratio of 2 to 4 equals ratio of 3 to 6,  $2/4 = 3/6$ : expressed thus,  $2 : 4 :: 3 : 6$ ; read, 2 is to 4 as 3 is to 6.

The first and fourth terms are called the extremes or outer terms, the second and third the means or inner terms.

The product of the means equals the product of the extremes:

$$2 : 4 :: 3 : 6; \quad 2 \times 6 = 12; \quad 3 \times 4 = 12.$$

Hence, given the first three terms to find the fourth, multiply the second and third terms together and divide by the first.

$$2 : 4 :: 3 : \text{what number?} \quad \text{Ans. } \frac{4 \times 3}{2} = 6.$$

**Algebraic expression of proportion.**— $a : b :: c : d$ ;  $\frac{a}{b} = \frac{c}{d}$ ;  $ad = bc$ ; from which  $a = \frac{bc}{d}$ ;  $d = \frac{bc}{a}$ ;  $b = \frac{ad}{c}$ ;  $c = \frac{ad}{b}$ .

**Mean proportional** between two given numbers, 1st and 2d, is such a number that the ratio which the first bears to it equals the ratio which it bears to the second. Thus,  $2 : 4 :: 4 : 8$ ; 4 is a mean proportional between 2 and 8. To find the mean proportional between two numbers, extract the square root of their product.

$$\text{Mean proportional of 2 and 8} = \sqrt{2 \times 8} = 4.$$

**Single Rule of Three**; or, finding the fourth term of a proportion when three terms are given.—Rule, as above, when the terms are stated in their proper order, multiply the second by the third and divide by the first. The difficulty is to state the terms in their proper order. The term which is of the same kind as the required or fourth term is made the third; the first and second must be like each other in kind and denomination. To determine which is to be made second and which first requires a little reasoning. If an inspection of the problem shows that the answer should be greater than the third term, then the greater of the other two given terms should be made the second term—otherwise the first. Thus, 3 men remove 54 cubic feet of rock in a day; how many men will remove in the same time 10 cubic yards? The answer is to be men—make men third term; the answer is to be more than three men, therefore make the greater quantity, 10 cubic yards, the second term; but as it is not the same denomination as the other term it must be reduced, = 270 cubic feet. The proportion is then stated:

$$54 : 270 :: 3 : x \text{ (the required number); } x = \frac{3 \times 270}{54} = 15 \text{ men.}$$

The problem is more complicated if we increase the number of given terms. Thus, in the above question, substitute for the words "in the same time" the words "in 3 days." First solve it as above, as if the work were to be done in the same time; then make another proportion, stating it thus: If 15 men do it in the same time, it will take fewer men to do it in 3 days; make 1 day the 2d term and 3 days the first term  $3 : 1 :: 15 \text{ men} : 5 \text{ men}$ .

**Compound Proportion, or Double Rule of Three.**—By this rule are solved questions like the one just given, in which two or more statings are required by the single rule of three. In it as in the single rule, there is one third term, which is of the same kind and denomination as the fourth or required term, but there may be two or more first and second terms. Set down the third term, take each pair of terms of the same kind separately, and arrange them as first and second by the same reasoning as is adopted in the single rule of three, making the greater of the pair the second if this pair considered alone should require the answer to be greater.

Set down all the first terms one under the other, and likewise all the second terms. Multiply all the first terms together and all the second terms together. Multiply the product of all the second terms by the third term, and divide this product by the product of all the first terms. Example: If 3 men remove 4 cubic yards in one day, working 12 hours a day, how many men working 10 hours a day will remove 20 cubic yards in 3 days?

$$\begin{array}{l} \text{Yards} \quad 4 : 20 \\ \text{Days} \quad 3 : 1 \\ \text{Hours} \quad 10 : 12 \end{array} : : 3 \text{ men.}$$

$$\text{Products } 120 : 240 :: 3 : 6 \text{ men. Ans.}$$

To abbreviate by cancellation, any one of the first terms may cancel either the third or any of the second terms; thus, 3 in first cancels 3 in third, making it 1, 10 cancels into 20 making the latter 2, which into 4 makes it 2, which into 12 makes it 6, and the figures remaining are only  $1 : 6 :: 1 : 6$ .

## INVOLUTION, OR POWERS OF NUMBERS.

**Involution** is the continued multiplication of a number by itself a given number of times. The number is called the root, or first power, and the products are called powers. The second power is called the square and

the third power the cube. The operation may be indicated without being performed by writing a small figure called the *index* or *exponent* to the right of and a little above the root; thus,  $3^3 =$  cube of 3,  $= 27$ .

To multiply two or more powers of the same number, add their exponents; thus,  $2^2 \times 2^3 = 2^5$ , or  $4 \times 8 = 32 = 2^5$ .

To divide two powers of the same number, subtract their exponents; thus,  $2^3 \div 2^2 = 2^1 = 2$ ;  $2^2 \div 2^4 = 2^{-2} = \frac{1}{2^2} = \frac{1}{4}$ . The exponent may thus be negative.

$2^3 + 2^3 = 2^0 = 1$ , whence the zero power of any number  $= 1$ . The first power of a number is the number itself. The exponent may be fractional, as  $2^{\frac{1}{2}}$ ,  $2^{\frac{2}{3}}$ , which means that the root is to be raised to a power whose exponent is the numerator of the fraction, and the root whose sign is the denominator is to be extracted (see Evolution). The exponent may be a decimal, as  $2^{0.5}$ ,  $2^{1.5}$ ; read, two to the five-tenths power, two to the one and five-tenths power. These powers are solved by means of Logarithms (which see).

**First Nine Powers of the First Nine Numbers.**

1st Pow'r	2d Pow'r	3d Power.	4th Power.	5th Power.	6th Power.	7th Power.	8th Power.	9th Power.

**EVOLUTION.**

**Evolution** is the finding of the root (or extracting the root) of any number the power of which is given.

The sign  $\sqrt{\quad}$  indicates that the square root is to be extracted:  $\sqrt[3]{\quad}$   $\sqrt[4]{\quad}$   $\sqrt[n]{\quad}$ , the cube root, 4th root, *n*th root.

A fractional exponent with 1 for the numerator of the fraction is also used to indicate that the operation of extracting the root is to be performed; thus,  $2^{\frac{1}{2}}$ ,  $2^{\frac{1}{3}} = \sqrt{2}$ ,  $\sqrt[3]{2}$ .

When the power of a number is indicated, the involution not being performed, the extraction of any root of that power may also be indicated by

dividing the index of the power by the index of the root, indicating the division by a fraction. Thus, extract the square root of the 6th power of 2:

$$\sqrt{2^6} = 2^{\frac{6}{2}} = 2^3 = 2^3 = 8.$$

The 6th power of 2, as in the table above, is 64;  $\sqrt{64} = 8$ .

Difficult problems in evolution are performed by logarithms, but the square root and the cube root may be extracted directly according to the rules given below. The 4th root is the square root of the square root. The 6th root is the cube root of the square root, or the square root of the cube root; the 9th root is the cube root of the cube root; etc.

**To Extract the Square Root.**—Point off the given number into periods of two places each, beginning with units. If there are decimals, point these off likewise, beginning at the decimal point, and supplying as many ciphers as may be needed. Find the greatest number whose square is less than the first left-hand period, and place it as the first figure in the quotient. Subtract its square from the left-hand period, and to the remainder annex the two figures of the second period for a dividend. Double the first figure of the quotient for a partial divisor; find how many times the latter is contained in the dividend exclusive of the right-hand figure, and set the figure representing that number of times as the second figure in the quotient, and annex it to the right of the partial divisor, forming the complete divisor. Multiply this divisor by the second figure in the quotient and subtract the product from the dividend. To the remainder bring down the next period and proceed as before, in each case doubling the figures in the root already found to obtain the trial divisor. Should the product of the second figure in the root by the completed divisor be greater than the dividend, erase the second figure both from the quotient and from the divisor, and substitute the next smaller figure, or one small enough to make the product of the second figure by the divisor less than or equal to the dividend.

$$\begin{array}{r} 3.1415926536 | 1.77245 + \\ \underline{1} \\ 27 | 214 \\ \underline{189} \\ 347 | 2515 \\ \underline{2429} \\ 3542 | 8692 \\ \underline{7084} \\ 35444 | 160865 \\ \underline{141776} \\ 354485 | 1908936 \\ \underline{1772425} \end{array}$$

To extract the square root of a fraction, extract the root of numerator and denominator separately.  $\sqrt{\frac{4}{9}} = \frac{2}{3}$ , or first convert the fraction into a

decimal,  $\sqrt{\frac{4}{9}} = \sqrt{.4444 +} = .6666 +$ .

**To Extract the Cube Root.**—Point off the number into periods of 3 figures each, beginning at the right hand, or unit's place. Point off decimals in periods of 3 figures from the decimal point. Find the greatest cube that does not exceed the left-hand period; write its root as the first figure in the required root. Subtract the cube from the left-hand period, and to the remainder bring down the next period for a dividend.

Square the first figure of the root; multiply by 300, and divide the product into the dividend for a trial divisor; write the quotient after the first figure of the root as a trial second figure.

Complete the divisor by adding to 300 times the square of the first figure, 30 times the product of the first by the second figure, and the square of the second figure. Multiply this divisor by the second figure; subtract the product from the remainder. (Should the product be greater than the remainder, the last figure of the root and the complete divisor are too large;

substitute for the last figure the next smaller number, and correct the trial divisor accordingly.)

To the remainder bring down the next period, and proceed as before to find the third figure of the root—that is, square the two figures of the root already found; multiply by 300 for a trial divisor, etc.

If at any time the trial divisor is greater than the dividend, bring down another period of 3 figures, and place 0 in the root and proceed.

The cube root of a number will contain as many figures as there are periods of 3 in the number.

**Shorter Methods of Extracting the Cube Root.**—1. From Wentworth's Algebra:

$$\begin{array}{r}
 \begin{array}{l}
 300 \times 1^2 = 300 \\
 30 \times 1 \times 2 = 60 \\
 2^2 = 4
 \end{array}
 \left. \begin{array}{l}
 \\
 \\
 \\
 \end{array} \right\} \begin{array}{r}
 300 \overline{) 881} \\
 \underline{60} \\
 364 \overline{) 728} \\
 \underline{64} \\
 153365
 \end{array} \\
 \\
 \begin{array}{l}
 300 \times 12^2 = 43200 \\
 30 \times 12 \times 3 = 1080 \\
 3^2 = 9
 \end{array}
 \left. \begin{array}{l}
 \\
 \\
 \\
 \end{array} \right\} \begin{array}{r}
 43200 \\
 \underline{1080} \\
 44289 \overline{) 132867} \\
 \underline{1080} \\
 20498963
 \end{array} \\
 \\
 \begin{array}{l}
 300 \times 123^2 = 4538700 \\
 30 \times 123 \times 4 = 14760 \\
 4^2 = 16
 \end{array}
 \left. \begin{array}{l}
 \\
 \\
 \\
 \end{array} \right\} \begin{array}{r}
 4538700 \\
 \underline{14760} \\
 4553476 \overline{) 18213904} \\
 \underline{14776} \\
 2285059625
 \end{array} \\
 \\
 \begin{array}{l}
 300 \times 1234^2 = 456826800 \\
 30 \times 1234 \times 5 = 185100 \\
 5^2 = 25
 \end{array}
 \left. \begin{array}{l}
 \\
 \\
 \\
 \end{array} \right\} \begin{array}{r}
 456826800 \\
 \underline{185100} \\
 457011925 \overline{) 2285059625}
 \end{array}
 \end{array}$$

After the first two figures of the root are found the next trial divisor is found by bringing down the sum of the 60 and 4 obtained in completing the preceding divisor, then adding the three lines connected by the brace, and annexing two ciphers. This method shortens the work in long examples, as is seen in the case of the last two trial divisors, saving the labor of squaring 123 and 1234. A further shortening of the work is made by obtaining the last two figures of the root by division, the divisor employed being three times the square of the part of the root already found; thus, after finding the first three figures:

$$\begin{array}{r}
 3 \times 123^2 = 45387 \overline{) 20498963} \overline{) 45.1 +} \\
 \underline{181548} \\
 234416 \\
 \underline{226935} \\
 74813
 \end{array}$$

The error due to the remainder is not sufficient to change the fifth figure of the root.

2. By Prof. H. A. Wood (*Stevens Indicator*, July, 1890):

I. Having separated the number into periods of three figures each, counting from the right, divide by the square of the nearest root of the first period, or first two periods; the nearest root is the trial root.

II. To the quotient obtained add twice the trial root, and divide by 3. This gives the root, or first approximation.

III. By using the first approximate root as a new trial root, and proceeding as before, a nearer approximation is obtained, which process may be repeated until the root has been extracted, or the approximation carried as far as desired.

**EXAMPLE.**—Required the cube root of 20. The nearest cube to 20 is  $3^3$ .

$$\begin{array}{r} 3^2 = 9)20.0 \\ \underline{2.2} \\ 6 \\ \underline{3)8.1} \\ 2.7 \text{ 1st T. R.} \end{array}$$

$$\begin{array}{r} 2.7^2 = 7.29)20.000 \\ \underline{2.743} \\ 5.4 \\ \underline{3)8.143} \\ 2.714, \text{ 1st ap. cube root.} \end{array}$$

$$\begin{array}{r} 2.714^2 = 7.365796)20.0000000 \\ \underline{2.7152534} \\ 5.428 \\ \underline{3)8.1432534} \\ 2.7144178 \text{ 2d ap. cube root.} \end{array}$$

**REMARK.**—In the example it will be observed that the second term, or first two figures of the root, were obtained by using for trial root the root of the first period. Using, in like manner, these two terms for trial root, we obtained four terms of the root; and these four terms for trial root gave seven figures of the root correct. In that example the last figure should be 7. Should we take these eight figures for trial root we should obtain at least fifteen figures of the root correct.

**To Extract a Higher Root than the Cube.**—The fourth root is the square root of the square root; the sixth root is the cube root of the square root or the square root of the cube root. Other roots are most conveniently found by the use of logarithms.

### ALLIGATION

shows the value of a mixture of different ingredients when the quantity and value of each is known.

Let the ingredients be  $a, b, c, d$ , etc., and their respective values per unit  $w, x, y, z$ , etc.

$$A = \text{the sum of the quantities} = a + b + c + d, \text{ etc.}$$

$$P = \text{mean value or price per unit of } A.$$

$$AP = aw + bx + cy + dz, \text{ etc.}$$

$$P = \frac{aw + bx + cy + dz}{A}.$$

### PERMUTATION

shows in how many positions any number of things may be arranged in a row; thus, the letters  $a, b, c$  may be arranged in six positions, viz.  $abc, acb, cab, cba, bac, bca$ .

**Rule.**—Multiply together all the numbers used in counting the things; thus, permutations of 1, 2, and 3 =  $1 \times 2 \times 3 = 6$ . In how many positions can 9 things in a row be placed?

$$1 \times 2 \times 3 \times 4 \times 5 \times 6 \times 7 \times 8 \times 9 = 362880.$$

### COMBINATION

shows how many arrangements of a few things may be made out of a greater number. **Rule:** Set down that figure which indicates the greater number, and after it a series of figures diminishing by 1, until as many are set down as the number of the few things to be taken in each combination. Then beginning under the last one set down said number of few things; then going backward set down a series diminishing by 1 until arriving under the first of the upper numbers. Multiply together all the upper numbers to form one product, and all the lower numbers to form another; divide the upper product by the lower one.

How many combinations of 9 things can be made, taking 3 in each combination ?

$$\frac{9 \times 8 \times 7}{1 \times 2 \times 3} = \frac{504}{6} = 84.$$

**ARITHMETICAL PROGRESSION,**

in a series of numbers, is a progressive increase or decrease in each successive number by the addition or subtraction of the same amount at each step, as 1, 2, 3, 4, 5, etc., or 15, 12, 9, 6, etc. The numbers are called terms, and the equal increase or decrease the difference. Examples in arithmetical progression may be solved by the following formulæ :

Let  $a$  = first term,  $l$  = last term,  $d$  = common difference,  $n$  = number of terms,  $s$  = sum of the terms:

$$\begin{aligned} l &= a + (n - 1)d, & &= -\frac{1}{2}d \pm \sqrt{2ds + \left(a - \frac{1}{2}d\right)^2} \\ &= \frac{2s}{n} - a, & &= \frac{s}{n} + \frac{(n - 1)d}{2}. \\ s &= \frac{1}{2}n[2a + (n - 1)d], & &= \frac{l + a}{2} + \frac{l^2 - a^2}{2d}, \\ &= (l + a)\frac{n}{2}, & &= \frac{1}{2}n[2l - (n - 1)d]. \\ a &= l - (n - 1)d, & &= \frac{s}{n} - \frac{(n - 1)d}{2}, \\ &= \frac{1}{2}d \pm \sqrt{\left(l + \frac{1}{2}d\right)^2 - 2ds}, & &= \frac{2s}{n} - l. \\ d &= \frac{l - a}{n - 1}, & &= \frac{2(s - an)}{n(n - 1)}, \\ &= \frac{l^2 - a^2}{2s - l - a}, & &= \frac{2(nl - s)}{n(n - 1)}. \\ r &= \frac{l - a}{d} + 1, & &= \frac{d - 2a \pm \sqrt{(2a - d)^2 + 8ds}}{2d}, \\ &= \frac{2s}{l + a}, & &= \frac{2l + d \pm \sqrt{(2l + d)^2 - 8ds}}{2d}. \end{aligned}$$

**GEOMETRICAL PROGRESSION,**

in a series of numbers, is a progressive increase or decrease in each successive number by the same multiplier or divisor at each step, as 1, 2, 4, 8, 16, etc., or 243, 81, 27, 9, etc. The common multiplier is called the ratio.

Let  $a$  = first term,  $l$  = last term,  $r$  = ratio or constant multiplier,  $n$  = number of terms,  $m$  = any term, as 1st, 2d, etc.,  $s$  = sum of the terms:

$$\begin{aligned} l &= ar^{n-1}, & &= \frac{a + (r - 1)s}{r}, & &= \frac{(r - 1)sr^{n-1}}{r^n - 1}, \\ \log l &= \log a + (n - 1) \log r, & & & & l(s - l)^{n-1} - a(s - a)^{n-1} = 0. \\ m &= ar^{m-1}. & & \log m &= \log a + (m - 1) \log r. \end{aligned}$$

$$s = \frac{a(r^n - 1)}{r - 1}, \quad = \frac{rl - a}{r - 1}, \quad = \frac{n - 1 \sqrt[n]{l^n} - n - 1 \sqrt[n]{a^n}}{n - 1 \sqrt[n]{l} - n - 1 \sqrt[n]{a}}, \quad = \frac{l^n - a}{r^n - a^n}.$$

$$a = \frac{l}{r^{n-1}}, \quad = \frac{(r-1)s}{r^{n-1}}, \quad \log a = \log l - (n-1) \log r.$$

$$r = \frac{n-1}{\sqrt[n]{\frac{l}{a}}}, \quad = \frac{s-a}{s-l}, \quad \log r = \frac{\log l - \log a}{n-1}$$

$$r^n - \frac{s}{a}r + \frac{s-a}{a} = 0, \quad r^n - \frac{s}{s-l}r^{n-1} + \frac{l}{s-l} = 0.$$

$$n = \frac{\log l - \log a}{\log r} + 1, \quad = \frac{\log [a + (r-1)s] - \log a}{\log r},$$

$$= \frac{\log l - \log a}{\log (s-a) - \log (s-l)} + 1, \quad = \frac{\log l - \log [lr - (r-1)s]}{\log r} + 1.$$

### Population of the United States.

(A problem in geometrical progression.)

Year.	Population.	Increase in 10 Years, per cent.	Annual Increase, per cent.
1860	31,443,321		
1870	39,818,449*	26.63	2.39
1880	50,155,783	25.96	2.33
1890	62,622,250	24.86	2.25
1900	76,295,220	21.834	1.994
1905	Est. 83,577,000		Est. 1.840
1910	" 91,554,000	Est. 20.0	" 1.840

### Estimated Population in Each Year from 1870 to 1909.

(Based on the above rates of increase, in even thousands.)

1870....	39,818	1880....	50,156	1890....	62,622	1900....	76,295
1871....	40,748	1881....	51,281	1891..	63,871	1901....	77,699
1872..	41,699	1882...	52,433	1892....	65,145	1902....	79,129
1873....	42,673	1883....	53,610	1893....	66,444	1903....	80,585
1874....	43,670	1884....	54,813	1894...	67,770	1904....	82,067
1875....	44,690	1885....	56,043	1895....	69,122	1905....	83,577
1876....	45,373	1886....	57,301	1896....	70,500	1906....	85,115
1877....	46,800	1887....	58,588	1897....	71,906	1907....	86,681
1878..	47,893	1888....	59,903	1898....	73,341	1908....	88,276
1879....	49,011	1889....	61,247	1899....	74,803	1909....	89,900

The above table has been calculated by logarithms as follows :

$$\log r = \log l - \log a + (n-1), \quad \log m = \log a + (m-1) \log r$$

$$\text{Pop. 1900.... } 76,295,220 \log = 7.8824988 \quad = \log l$$

$$\text{" 1890... } 62,622,250 \log = 7.7967285 \quad = \log a$$

$$\text{diff.} = .0857703$$

$$n = 11, n - 1 = 10; \text{ diff. } + 10 = .00857703 \quad = \log r,$$

$$\text{add log for 1890 } 7.7967285 \quad = \log a$$

$$\text{log for 1891} = 7.80530553 \text{ No.} = 63,871 \dots$$

$$\text{add again } .00857703$$

$$\text{log for 1892 } 7.81388256 \text{ No.} = 65,145 \dots$$

**Compound interest** is a form of geometrical progression ; the ratio being 1 plus the percentage.

\* Corrected by addition of 1,260,078, estimated error of the census of 1870, Census Bulletin No. 16, Dec. 12, 1890.

**INTEREST AND DISCOUNT.**

**Interest** is money paid for the use of money for a given time; the factors are:

- $p$ , the sum loaned, or the principal;  
 $t$ , the time in years;  
 $r$ , the rate of interest;  
 $i$ , the amount of interest for the given rate and time;  
 $a = p + i$  = the amount of the principal with interest at the end of the time.

Formulæ :

$$i = \text{interest} = \text{principal} \times \text{time} \times \text{rate per cent} = i = \frac{ptr}{100};$$

$$a = \text{amount} = \text{principal} + \text{interest} = p + \frac{ptr}{100};$$

$$r = \text{rate} = \frac{100i}{pt};$$

$$p = \text{principal} = \frac{100i}{tr} = a - \frac{ptr}{100};$$

$$t = \text{time} = \frac{100i}{pr}.$$

If the rate is expressed decimally as a per cent,—thus, 6 per cent = .06,—the formulæ become

$$i = prt; \quad a = p(1 + rt); \quad r = \frac{i}{pt}; \quad t = \frac{i}{pr}; \quad p = \frac{i}{tr} = \frac{a}{1 + rt}.$$

**Rules for finding Interest.**—Multiply the principal by the rate per annum divided by 100, and by the time in years and fractions of a year.

If the time is given in days, interest =  $\frac{\text{principal} \times \text{rate} \times \text{no. of days}}{365 \times 100}$ .

In banks interest is sometimes calculated on the basis of 360 days to a year, or 12 months of 30 days each.

Short rules for interest at 6 per cent, when 360 days are taken as 1 year:

Multiply the principal by number of days and divide by 6000.

Multiply the principal by number of months and divide by 200.

The interest of 1 dollar for one month is  $\frac{1}{2}$  cent.

**Interest of 100 Dollars for Different Times and Rates.**

Time.	2%	3%	4%	5%	6%	8%	10%
1 year	\$2.00	\$3.00	\$4.00	\$5.00	\$6.00	\$8.00	\$10.00

**Discount** is interest deducted for payment of money before it is due.

**True discount** is the difference between the amount of a debt payable at a future date without interest and its present worth. The present worth is that sum which put at interest at the legal rate will amount to the debt when it is due.

To find the present worth of an amount due at future date, divide the amount by the amount of \$1 placed at interest for the given time. The discount equals the amount minus the present worth.

What discount should be allowed on \$103 paid six months before it is due, interest being 6 per cent per annum ?

$$\frac{103}{1 + 1 \times .06 \times \frac{1}{2}} = \$100 \text{ present worth, discount} = 3.00.$$

**Bank discount** is the amount deducted by a bank as interest on money loaned on promissory notes. It is interest calculated not on the actual sum loaned, but on the gross amount of the note, from which the discount is deducted in advance. It is also calculated on the basis of 360 days in the year, and for 3 (in some banks 4) days more than the time specified in the note. These are called days of grace, and the note is not payable till the last of these days. In some States days of grace have been abolished.

What discount will be deducted by a bank in discounting a note for \$103 payable 6 months hence? Six months = 182 days, add 3 days grace = 185 days,  $\frac{103 \times 185}{6000} = \$3.176$ .

**Compound Interest.**—In compound interest the interest is added to the principal at the end of each year, (or shorter period if agreed upon).

Let  $p$  = the principal,  $r$  = the rate expressed decimally,  $n$  = no of years, and  $a$  the amount:

$$a = \text{amount} = p(1+r)^n; \quad r = \text{rate} = \sqrt[n]{\frac{a}{p}} - 1,$$

$$p = \text{principal} = \frac{a}{(1+r)^n}; \quad \text{no. of years} = n = \frac{\log a - \log p}{\log(1+r)}.$$

### Compound Interest Table.

(Value of one dollar at compound interest, compounded yearly, at 3, 4, 5, and 6 per cent, from 1 to 50 years.)

Years.	3%	4%	5%	6%	Years.	3%	4%	5%	6%
1	1.03	1.04	1.05	1.06	16	1.6047	1.8730	2.1829	2.5403

At compound interest at 3 per cent money will double itself in  $23\frac{1}{2}$  years, at 4 per cent in  $17\frac{2}{3}$  years, at 5 per cent in 14.2 years, and at 6 per cent in 11.9 years.

### EQUATION OF PAYMENTS.

By equation of payments we find the equivalent or average time in which one payment should be made to cancel a number of obligations due at different dates; also the number of days upon which to calculate interest or discount upon a gross sum which is composed of several smaller sums payable at different dates.

**Rule.**—Multiply each item by the time of its maturity in days from a fixed date, taken as a standard, and divide the sum of the products by the sum of the items: the result is the average time in days from the standard date.

A owes B \$100 due in 30 days, \$200 due in 60 days, and \$300 due in 90 days. In how many days may the whole be paid in one sum of \$600?

$$100 \times 30 + 200 \times 60 + 300 \times 90 = 42,000; \quad 42,000 \div 600 = 70 \text{ days, ans.}$$

A owes B \$100, \$200, and \$300, which amounts are overdue respectively 30, 60, and 90 days. If he now pays the whole amount, \$600, how many days' interest should he pay on that sum? *Ans.* 70 days.

**PARTIAL PAYMENTS.**

To compute interest on notes and bonds when partial payments have been made:

**United States Rule.**—Find the amount of the principal to the time of the first payment, and, subtracting the payment from it, find the amount of the remainder as a new principal to the time of the next payment.

If the payment is less than the interest, find the amount of the principal to the time when the sum of the payments equals or exceeds the interest due, and subtract the sum of the payments from this amount.

Proceed in this manner till the time of settlement.

**Note.**—The principles upon which the preceding rule is founded are:

1st. That payments must be applied first to discharge accrued interest, and then the remainder, if any, toward the discharge of the principal.

2d. That only unpaid principal can draw interest.

**Mercantile Method.**—When partial payments are made on short notes or interest accounts, business men commonly employ the following method:

Find the amount of the whole debt to the time of settlement; also find the amount of each payment from the time it was made to the time of settlement. Subtract the amount of payments from the amount of the debt; the remainder will be the balance due.

**ANNUITIES.**

An **Annuity** is a fixed sum of money paid yearly, or at other equal times agreed upon. The values of annuities are calculated by the principles of compound interest.

1. Let  $i$  denote interest on \$1 for a year, then at the end of a year the amount will be  $1 + i$ . At the end of  $n$  years it will be  $(1 + i)^n$ .

2. The sum which in  $n$  years will amount to 1 is  $\frac{1}{(1 + i)^n}$  or  $(1 + i)^{-n}$ , or the present value of 1 due in  $n$  years.

3. The amount of an annuity of 1 in any number of years  $n$  is  $\frac{(1 + i)^n - 1}{i}$ .

4. The present value of an annuity of 1 for any number of years  $n$  is  $\frac{1 - (1 + i)^{-n}}{i}$ .

5. The annuity which 1 will purchase for any number of years  $n$  is  $\frac{i}{1 - (1 + i)^{-n}}$ .

6. The annuity which would amount to 1 in  $n$  years is  $\frac{i}{(1 + i)^n - 1}$ .

**Amounts, Present Values, etc., at 5% Interest.**

Years	(1) $(1 + i)^n$	(2) $(1 + i)^{-n}$	(3) $\frac{(1 + i)^n - 1}{i}$	(4) $\frac{1 - (1 + i)^{-n}}{i}$	(5) $\frac{i}{1 - (1 + i)^{-n}}$	(6) $\frac{i}{(1 + i)^n - 1}$

## TABLES FOR CALCULATING SINKING-FUNDS AND PRESENT VALUES.

Engineers and others connected with municipal work and industrial enterprises often find it necessary to calculate payments to sinking-funds which will provide a sum of money sufficient to pay off a bond issue or other debt at the end of a given period, or to determine the present value of certain annual charges. The accompanying tables were computed by Mr. John W. Hill, of Cincinnati, *Eng'g News*, Jan. 25, 1894.

Table I (opposite page) shows the annual sum at various rates of interest required to net \$1000 in from 2 to 50 years, and Table II shows the present value at various rates of interest of an annual charge of \$1000 for from 5 to 50 years, at five-year intervals and for 100 years.

**Table II.—Capitalization of Annuity of \$1000 for from 5 to 100 Years.**

Years.	Rate of Interest, per cent.							
	2½	3	3½	4	4½	5	5½	6
5	4,645.88	4,579.60	4,514.92	4,451.68	4,389.91	4,329.45	4,268.09	4,212.40

## WEIGHTS AND MEASURES.

### Long Measure.—Measures of Length.

12 inches = 1 foot.

3 feet = 1 yard.

1760 yards, or 5280 feet = 1 mile.

Additional measures of length in occasional use: 1000 mils = 1 inch; 4 inches = 1 hand; 9 inches = 1 span; 2½ feet = 1 military pace; 2 yards = 1 fathom; 5½ yards, or 16½ feet = 1 rod (formerly also called pole or perch).

**Old Land Measure.**—7.92 inches = 1 link; 100 links, or 66 feet, or 4 rods = 1 chain; 10 chains, or 220 yards = 1 furlong; 8 furlongs = 1 mile; 10 square chains = 1 acre.

### Nautical Measure.

6080.26 feet, or 1.15156 statute miles } = 1 nautical mile, or knot.\*

3 nautical miles = 1 league.

60 nautical miles, or 69.168 statute miles } = 1 degree (at the equator).

360 degrees = circumference of the earth at the equator.

\*The British Admiralty takes the round figure of 6080 ft. which is the length of the "measured mile" used in trials of vessels. The value varies from 6080.26 to 6088.44 ft. according to different measures of the earth's diameter. There is a difference of opinion among writers as to the use of the word "knot" to mean length or a distance—some holding that it should be used only to denote a rate of speed. The length between knots on the log line is 1/120 of a nautical mile, or 50.7 ft., when a half-minute glass is used; so that a speed of 10 knots is equal to 10 nautical miles per hour.

**Square Measure.—Measures of Surface.**

144 square inches, or 183.35 circular inches	}	= 1 square foot.
9 square feet		
$30\frac{1}{4}$ square yards, or $272\frac{1}{4}$ square feet	}	= 1 square rod.
10 sq. chains, or 160 sq. rods, or 4840 sq. yards, or 43560 sq. feet,		
640 acres		

An acre equals a square whose side is 208.71 feet.

**Circular Inch; Circular Mil.**—A circular inch is the area of a circle 1 inch in diameter = 0.7854 square inch.

1 square inch = 1.2732 circular inches.

A circular mil is the area of a circle 1 mil, or .001 inch in diameter. 1000<sup>2</sup> or 1,000,000 circular mils = 1 circular inch.

1 square inch = 1,273,239 circular mils.

The mil and circular mil are used in electrical calculations involving the diameter and area of wires.

**Solid or Cubic Measure.—Measures of Volume.**

1728 cubic inches = 1 cubic foot.

27 cubic feet = 1 cubic yard.

1 cord of wood = a pile,  $4 \times 4 \times 8$  feet = 128 cubic feet.

1 perch of masonry =  $16\frac{1}{2} \times 1\frac{1}{2} \times 1$  foot =  $24\frac{3}{4}$  cubic feet.

**Liquid Measure.**

4 gills	= 1 pint.	
2 pints	= 1 quart.	
4 quarts	= 1 gallon	{ U. S. 231 cubic inches. Eng. 277.274 cubic inches.
$31\frac{1}{2}$ gallons	= 1 barrel.	
42 gallons	= 1 tierce.	
2 barrels, or 63 gallons	= 1 hogshead.	
84 gallons, or 2 tierces	= 1 puncheon.	
2 hogsheads, or 126 gallons	= 1 pipe or butt.	
2 pipes, or 3 puncheons	= 1 tun.	

A gallon of water at 62° F. weighs 8.3356 lbs.

The U. S. gallon contains 231 cubic inches; 7.4805 gallons = 1 cubic foot. A cylinder 7 in. diam. and 6 in. high contains 1 gallon, very nearly, or 230.9 cubic inches. The British Imperial gallon contains 277.274 cubic inches = 1.20032 U. S. gallon, or 10 lbs. of water at 62° F.

**The Miner's Inch.**—(Western U. S. for measuring flow of a stream of water).

The Miner's Inch is more or less indefinite, for the reason that California water companies do not all use the same head above the centre of the aperture, and the inch varies from 1.36 to 1.73 cubic feet per minute each; but the most common measurement is through an aperture 2 inches high and whatever length is required, and through a plank  $1\frac{1}{2}$  inches thick. The lower edge of the aperture should be 2 inches above the bottom of the measuring-box, and the plank 5 inches high above the aperture, thus making a 6-inch head above the centre of the stream. Each square inch of this opening represents a miner's inch, which is equal to a flow of  $1\frac{1}{2}$  cubic feet per minute.

**Apothecaries' Fluid Measure.**

60 minims = 1 fluid drachm.

8 drachms = 1 fluid ounce.

In the U. S. a fluid ounce is the 128th part of a U. S. gallon, or 1.805 cu. ins. It contains 456.3 grains of water at 39° F. In Great Britain the fluid ounce is 1.732 cu. ins. and contains 1 ounce avoirdupois, or 437.5 grains of water at 62° F.

**Dry Measure, U. S.**

2 pints = 1 quart.

8 quarts = 1 peck.

4 pecks = 1 bushel.

The standard U. S. bushel is the Winchester bushel, which is in cylinder

form,  $18\frac{1}{2}$  inches diameter and 8 inches deep, and contains 2150.42 cubic inches.

A struck bushel contains 2150.42 cubic inches = 1.2445 cu. ft.; 1 cubic foot = 0.80356 struck bushel. A heaped bushel is a cylinder  $18\frac{1}{2}$  inches diameter and 8 inches deep, with a heaped cone not less than 6 inches high. It is equal to  $1\frac{1}{4}$  struck bushels.

The British Imperial bushel is based on the Imperial gallon, and contains 8 such gallons, or 2218.192 cubic inches = 1.2837 cubic feet. The English quarter = 8 Imperial bushels.

Capacity of a cylinder in U. S. gallons = square of diameter, in inches  $\times$  height in inches  $\times$  .0034. (Accurate within 1 part in 100,000.)

Capacity of a cylinder in U. S. bushels = square of diameter in inches  $\times$  height in inches  $\times$  .0003652.

### Shipping Measure.

*Register Ton.*—For register tonnage or for measurement of the entire internal capacity of a vessel:

100 cubic feet = 1 register ton.

This number is arbitrarily assumed to facilitate computation.

*Shipping Ton.*—For the measurement of cargo:

40 cubic feet =	{	1 U. S. shipping ton. 31.16 Imp. bushels. 32.143 U. S. " "
42 cubic feet =	{	1 British shipping ton. 32.719 Imp. bushels. 33.75 U. S. " "

*Carpenter's Rule.*—Weight a vessel will carry = length of keel  $\times$  breadth at main beam  $\times$  depth of hold in feet  $\div$  95 (the cubic feet allowed for a ton). The result will be the tonnage. For a double-decker instead of the depth of the hold take half the breadth of the beam.

### Measures of Weight.—Avoirdupois, or Commercial Weight.

16 drachms, or 437.5 grains	= 1 ounce, oz.
16 ounces, or 7000 grains	= 1 pound, lb.
28 pounds	= 1 quarter, qr.
4 quarters	= 1 hundredweight, cwt. = 112 lbs.
20 hundred weight	= 1 ton of 2240 pounds, or long ton.
2000 pounds	= 1 net, or short ton.
2204.6 pounds	= 1 metric ton.
1 stone = 14 pounds ; 1 quintal = 100 pounds.	

The drachm, quarter, hundredweight, stone, and quintal are now seldom used in the United States.

### Troy Weight.

24 grains	= 1 pennyweight, dwt.
20 pennyweights	= 1 ounce, oz. = 480 grains.
12 ounces	= 1 pound, lb. = 5760 grains.

Troy weight is used for weighing gold and silver. The grain is the same in Avoirdupois, Troy, and Apothecaries' weights. A carat, used in weighing diamonds = 3.168 grains = .205 gramme.

### Apothecaries' Weight.

20 grains	= 1 scruple, $\mathfrak{S}$
3 scruples = 1 drachm, $\mathfrak{z}$	= 60 grains.
8 drachms = 1 ounce, $\mathfrak{ʒ}$	= 480 grains.
12 ounces = 1 pound, lb.	= 5760 grains.

**To determine whether a balance has unequal arms.**—After weighing an article and obtaining equilibrium, transpose the article and the weights. If the balance is true, it will remain in equilibrium; if untrue, the pan suspended from the longer arm will descend.

**To weigh correctly on an incorrect balance.**—First, by substitution. Put the article to be weighed in one pan of the balance and

counterpoise it by any convenient heavy articles placed on the other pan. Remove the article to be weighed and substitute for it standard weights until equipoise is again established. The amount of these weights is the weight of the article.

Second, by transposition. Determine the apparent weight of the article as usual, then its apparent weight after transposing the article and the weights. If the difference is small, add half the difference to the smaller of the apparent weights to obtain the true weight. If the difference is 2 per cent the error of this method is 1 part in 10,000. For larger differences, or to obtain a perfectly accurate result, multiply the two apparent weights together and extract the square root of the product.

### Circular Measure.

60 seconds, "	= 1 minute, '.
60 minutes, '	= 1 degree, °.
90 degrees	= 1 quadrant.
360 "	= circumference.

### Time.

60 seconds	= 1 minute.
60 minutes	= 1 hour.
24 hours	= 1 day.
7 days	= 1 week.

365 days, 5 hours, 48 minutes, 48 seconds = 1 year.

By the Gregorian Calendar every year whose number is divisible by 4 is a leap year, and contains 366 days, the other years containing 365 days, except that the centesimal years are leap years only when the number of the year is divisible by 400.

The comparative values of mean solar and sidereal time are shown by the following relations according to Bessel :

365.24222 mean solar days	= 366.24222 sidereal days, whence
1 mean solar day	= 1.00273791 sidereal days;
1 sidereal day	= 0.99726957 mean solar day;
24 hours mean solar time	= 24 <sup>h</sup> 3 <sup>m</sup> 56 <sup>s</sup> .555 sidereal time;
24 hours sidereal time	= 23 <sup>h</sup> 56 <sup>m</sup> 4 <sup>s</sup> .091 mean solar time,

whence 1 mean solar day is 3<sup>m</sup> 55<sup>s</sup>.91 longer than a sidereal day, reckoned in mean solar time.

## BOARD AND TIMBER MEASURE.

### Board Measure.

In board measure boards are assumed to be one inch in thickness. To obtain the number of feet board measure (B. M.) of a board or stick of square timber, multiply together the length in feet, the breadth in feet, and the thickness in inches.

**To compute the measure or surface in square feet.**—When all dimensions are in feet, multiply the length by the breadth, and the product will give the surface required.

When either of the dimensions are in inches, multiply as above and divide the product by 12.

When all dimensions are in inches, multiply as before and divide product by 144.

### Timber Measure.

**To compute the volume of round timber.**—When all dimensions are in feet, multiply the length by one quarter of the product of the mean girth and diameter, and the product will give the measurement in cubic feet. When length is given in feet and girth and diameter in inches, divide the product by 144; when all the dimensions are in inches, divide by 1728.

**To compute the volume of square timber.**—When all dimensions are in feet, multiply together the length, breadth, and depth; the product will be the volume in cubic feet. When one dimension is given in inches, divide by 12; when two dimensions are in inches, divide by 144; when all three dimensions are in inches, divide by 1728.

**Contents in Feet of Joists, Scantling, and Timber.**

**FRENCH OR METRIC MEASURES.**

The metric unit of length is the metre = 39.37 inches.

The metric unit of weight is the gram = 15.432 grains.

The following prefixes are used for subdivisions and multiples; Milli =  $\frac{1}{1000}$ , Centi =  $\frac{1}{100}$ , Deci =  $\frac{1}{10}$ , Deca = 10, Hecto = 100, Kilo = 1000, Myria = 10,000.

**FRENCH AND BRITISH (AND AMERICAN) EQUIVALENT MEASURES.**

**Measures of Length.**

FRENCH.	BRITISH and U. S.
1 metre	= 39.37 inches, or 3.28083 feet, or 1.09361 yards.
.3048 metre	= 1 foot.
1 centimetre	= .3937 inch.
2.54 centimetres	= 1 inch.
1 millimetre	= .03937 inch, or 1/25 inch, nearly.
25.4 millimetres	= 1 inch.
1 kilometre	= 1093.61 yards, or 0.62137 mile.

**Measures of Surface.**

FRENCH.	BRITISH and U. S.
1 square metre	= { 10.764 square feet, 1.196 square yards.
.836 square metre	= 1 square yard.
.0929 square metre	= 1 square foot.
1 square centimetre	= .155 square inch.
6.452 square centimetres	= 1 square inch.
1 square millimetre	= .00155 sq. in. = 1973.5 circ. mils.
645.2 square millimetres	= 1 square inch.
1 centiare = 1 sq. metre	= 10 764 square feet.
1 are = 1 sq. decametre	= 1076.41 " "
1 hectare = 100 ares	= 107641 " " = 2.4711 acres.
1 sq. kilometre	= .386109 sq. miles = 247.11 "
1 sq. myriametre	= 38.6109 " "

**Of Volume.**

FRENCH.	BRITISH and U. S.
1 cubic metre	= { 35.314 cubic feet, 1.308 cubic yards.
.7645 cubic metre	= 1 cubic yard.
.02832 cubic metre	= 1 cubic foot.
1 cubic decimetre	= { 61.023 cubic inches, .0353 cubic foot.
28.32 cubic decimetres	= 1 cubic foot.
1 cubic centimetre	= .061 cubic inch.
16.387 cubic centimetres	= 1 cubic inch.
1 cubic centimetre = 1 millilitre	= .061 cubic inch.
1 centilitre =	= .610 " "
1 decilitre =	= 6.102 " "
1 litre = 1 cubic decimetre	= 61.023 " " = 1.05671 quarts, U. S.
1 hectolitre or decistere	= 3.5314 cubic feet = 2.8375 bushels, "
1 stere, kilolitre, or cubic metre	= 1.308 cubic yards = 28.37 bushels, "

**Of Capacity.**

FRENCH.	BRITISH and U. S.
1 litre (= 1 cubic decimetre)	= { 61.023 cubic inches, .03531 cubic foot, .2642 gallon (American), 2.202 pounds of water at 62° F.
28.317 litres	= 1 cubic foot.
4.543 litres	= 1 gallon (British).
3.785 litres	= 1 gallon (American).

**Of Weight.**

FRENCH.	BRITISH and U. S.
1 gramme	= 15.432 grains.
.0648 gramme	= 1 grain.
28.35 gramme	= 1 ounce avoirdupois.
1 kilogramme	= 2.2046 pounds.
.4536 kilogramme	= 1 pound.
1 tonne or metric ton	= { .9842 ton of 2240 pounds, 19.68 cwt.,
1000 kilogrammes	= { 2204.6 pounds.
1.016 metric tons	= { 1 ton of 2240 pounds.
1016 kilogrammes	= {

Mr. O. H. Titmann, in Bulletin No. 9 of the U. S. Coast and Geodetic Survey, discusses the work of various authorities who have compared the yard and the metre, and by referring all the observations to a common standard has succeeded in reconciling the discrepancies within very narrow limits. The following are his results for the number of inches in a metre according to the comparisons of the authorities named:

1817.	Hassler.....	39.36994 inches.
1818.	Kater.....	39.36990 "
1835.	Baily.....	39.36973 "
1866.	Clarke.....	39.36970 "
1885.	Comstock.....	39.36984 "
	The mean of these is.....	39.36982 "

**METRIC CONVERSION TABLES.**

The following tables, with the subjoined memoranda, were published in 1890 by the United States Coast and Geodetic Survey, office of standard weights and measures, T. C. Mendenhall, Superintendent.

**Tables for Converting U. S. Weights and Measures—  
Customary to Metric.**

The only authorized material standard of customary length is the Troughton scale belonging to this office, whose length at 59°.62 Fahr. conforms to the British standard. The yard in use in the United States is therefore equal to the British yard.

The only authorized material standard of customary weight is the Troy pound of the mint. It is of brass of unknown density, and therefore not suitable for a standard of mass. It was derived from the British standard Troy pound of 1758 by direct comparison. The British Avoirdupois pound was also derived from the latter, and contains 7000 grains Troy.

The grain Troy is therefore the same as the grain Avoirdupois, and the pound Avoirdupois in use in the United States is equal to the British pound Avoirdupois.

The metric system was legalized in the United States in 1866.

By the concurrent action of the principal governments of the world an International Bureau of Weights and Measures has been established near Paris.

The International Standard Metre is derived from the Mètre des Archives, and its length is defined by the distance between two lines at 0° Centigrade, on a platinum-iridium bar deposited at the International Bureau.

The International Standard Kilogramme is a mass of platinum-iridium deposited at the same place, and its weight *in vacuo* is the same as that of the Kilogramme des Archives.

Copies of these international standards are deposited in the office of standard weights and measures of the U. S. Coast and Geodetic Survey.

The litre is equal to a cubic decimetre of water, and it is measured by the quantity of distilled water which, at its maximum density, will counterpoise the standard kilogramme in a vacuum; the volume of such a quantity of water being, as nearly as has been ascertained, equal to a cubic decimetre.

**COMPOUND UNITS.**

**Measures of Pressure and Weight.**

1 lb. per square inch.	=	{	144 lbs. per square foot.
			2.0355 ins. of mercury at 32° F.
			2.0416 " " " 62° F.
			2.309 ft. of water at 62° F.
			27.71 ins. " " " 62° F.
1 ounce per sq. in.	=	{	.1276 in. of mercury at 62° F.
			1.732 ins. of water at 62° F.
1 atmosphere (14.7 lbs. per sq. in.)	=	{	2116.3 lbs. per square foot.
			33.947 ft. of water at 62° F.
			30 ins. of mercury at 62° F.
			29.922 ins. of mercury at 32° F.
			760 millimetres of mercury at 32° F.
1 inch of water at 62° F.	=	{	.03609 lb. or .5774 oz. per sq. in.
			5.196 lbs. per square foot.
			.0736 in. of mercury at 62° F.
1 inch of water at 32° F.	=	{	5.2021 lbs. per square foot.
			.036125 lb. " " inch.
1 foot of water at 62° F.	=	{	.433 lb. per square inch.
			62.355 lbs. " " foot.
1 inch of mercury at 62° F.	=	{	.491 lb. or 7.86 oz. per sq. in.
			1.132 ft. of water at 62° F.
			13.58 ins. " " " 62° F.

**Weight of One Cubic Foot of Pure Water.**

At 32° F. (freezing-point).....	62.418 lbs.
" 39.1° F. (maximum density).....	62.425 "
" 62° F. (standard temperature).....	62.355 "
" 212° F. (boiling-point, under 1 atmosphere).....	59.76 "
American gallon = 231 cubic ins. of water at 62° F. =	8.3356 lbs.
British " = 277.274 " " " " " " =	10 lbs.

**Measures of Work, Power, and Duty.**

**Work.**—The sustained exertion of pressure through space.

**Unit of work.**—One foot-pound, i.e., a pressure of one pound exerted through a space of one foot.

**Horse-power.**—The rate of work. Unit of horse-power = 33,000 ft.-lbs. per minute, or 550 ft.-lbs. per second = 1,980,000 ft.-lbs. per hour.

**Heat unit** = heat required to raise 1 lb. of water 1° F. (from 39° to 40°).

Horse-power expressed in heat units =  $\frac{33000}{778}$  = 42.416 heat units per minute = .707 heat unit per second = 2545 heat units per hour.

1 lb. of fuel per H. P. per hour = { 1,980,000 ft.-lbs. per lb. of fuel.  
2,545 heat units " " }

1,000,000 ft.-lbs. per lb. of fuel = 1.98 lbs. of fuel per H. P. per hour.

**Velocity.**—Feet per second =  $\frac{5280}{3600}$  =  $\frac{22}{15}$  × miles per hour.

**Gross tons per mile** =  $\frac{1760}{2240}$  =  $\frac{11}{14}$  lbs. per yard (single rail.)

**French and British Equivalents of Compound Units.**

FRENCH.		BRITISH.
1 gramme per square millimetre	=	1.422 lbs. per square inch.
1 kilogramme per square " "	=	1422 32 " " " "
1 " " " centimetre	=	14.223 " " " "
1.0335 kg. per sq. cm. = 1 atmosphere	=	14.7 " " " "
0.070308 kilogramme per square centimetre	=	1 lb. per square inch.
1 gramme per litre	=	0.062428 lb. per cubic foot.
1 kilogrammetre	=	7.2330 foot-pounds.

The Stubs' Steel Wire Gauge is used in measuring drawn steel wire or drill rods of Stubs' make, and is also used by many makers of American drill rods,

## THE EDISON OR CIRCULAR MIL WIRE GAUGE.

(For table of copper wires by this gauge, giving weights, electrical resistances, etc., see Copper Wire.)

Mr. C. J. Field (*Stevens Indicator*, July, 1887) thus describes the origin of the Edison gauge:

The Edison company experienced inconvenience and loss by not having a wide enough range nor sufficient number of sizes in the existing gauges. This was felt more particularly in the central-station work in making electrical determinations for the street system. They were compelled to make use of two of the existing gauges at least, thereby introducing a complication that was liable to lead to mistakes by the contractors and linemen.

In the incandescent system an even distribution throughout the entire system and a uniform pressure at the point of delivery are obtained by calculating for a given maximum percentage of loss from the potential as delivered from the dynamo. In carrying this out, on account of lack of regular sizes, it was often necessary to use larger sizes than the occasion demanded, and even to assume new sizes for large underground conductors. It was also found that nearly all manufacturers based their calculation for the conductivity of their wire on a variety of units, and that not one used the latest unit as adopted by the British Association and determined from Dr. Matthiessen's experiments; and as this was the unit employed in the manufacture of the Edison lamps, there was a further reason for constructing a new gauge. The engineering department of the Edison company, knowing the requirements, have designed a gauge that has the widest range obtainable and a large number of sizes which increase in a regular and uniform manner. The basis of the graduation is the sectional area, and the number of the wire corresponds. A wire of 100,000 circular mils area is No. 100; a wire of one half the size will be No. 50; twice the size No. 200.

In the older gauges, as the number increased the size decreased. With this gauge, however, the number increases with the wire, and the number multiplied by 1000 will give the circular mils.

The weight per mil-foot, 0.0000302705 pounds, agrees with a specific gravity of 8.889, which is the latest figure given for copper. The ampere capacity which is given was deduced from experiments made in the company's laboratory, and is based on a rise of temperature of 50° F. in the wire.

In 1893 Mr. Field writes, concerning gauges in use by electrical engineers:

The B. and S. gauge seems to be in general use for the smaller sizes, up to 100,000 c. m., and in some cases a little larger. From between one and two hundred thousand circular mils upwards, the Edison gauge or its equivalent is practically in use, and there is a general tendency to designate all sizes above this in circular mils, specifying a wire as 200,000, 400,000, 500,000, or 1,000,000 c. m.

In the electrical business there is a large use of copper wire and rod and other materials of these large sizes, and in ordering them, speaking of them, specifying, and in every other use, the general method is to simply specify the circular milage. I think it is going to be the only system in the future for the designation of wires, and the attaining of it means practically the adoption of the Edison gauge or the method and basis of this gauge as the correct one for wire sizes.

## THE U. S. STANDARD GAUGE FOR SHEET AND PLATE IRON AND STEEL, 1893.

There is in this country no uniform or standard gauge, and the same numbers in different gauges represent different thicknesses of sheets or plates. This has given rise to much misunderstanding and friction between employers and workmen and mistakes and fraud between dealers and consumers.

An Act of Congress in 1893 established the Standard Gauge for sheet iron and steel which is given on the next page. It is based on the fact that a cubic foot of iron weighs 480 pounds.

A sheet of iron 1 foot square and 1 inch thick weighs 40 pounds, or 640 ounces, and 1 ounce in weight should be 1/640 inch thick. The scale has been arranged so that each descriptive number represents a certain number of ounces in weight and an equal number of 640ths of an inch in thickness.

The law enacts that on and after July 1, 1893, the new gauge shall be used in determining duties and taxes levied on sheet and plate iron and steel; and that in its application a variation of 2½ per cent either way may be allowed.

**U. S. STANDARD GAUGE FOR SHEET AND PLATE  
IRON AND STEEL, 1893.**

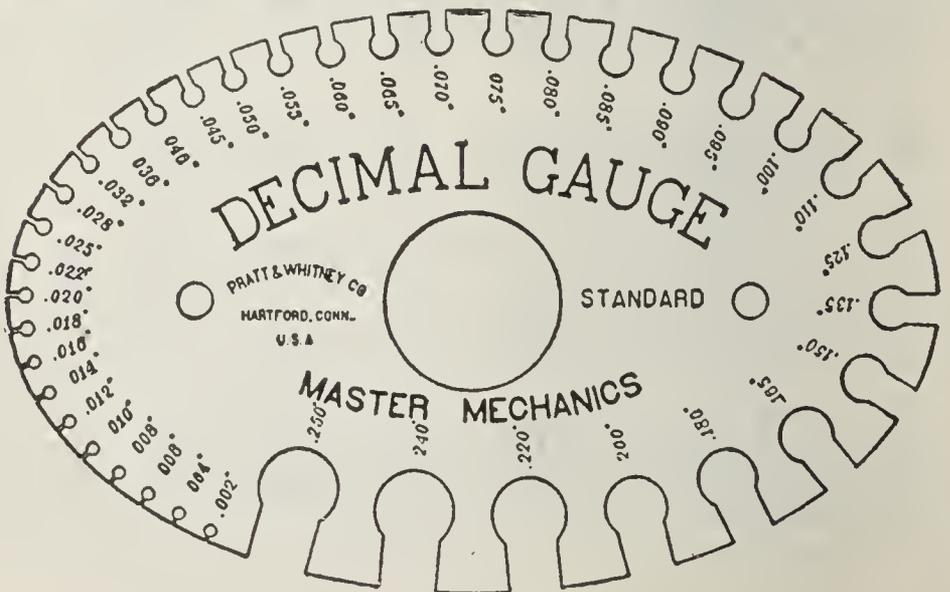

Number of Gauge.	Approximate Thickness in Fractions of an Inch.	Approximate Thickness in Decimal Parts of an Inch.	Approximate Thickness in Millimeters.	Weight per Square Foot in Ounces Avoirdupois.	Weight per Square Foot in Pounds Avoirdupois.	Weight per Square Foot in Kilograms.	Weight per Square Meter in Kilograms.	Weight per Square Meter in Pounds Avoirdupois.

**The Decimal Gauge.**—The legalization of the standard sheet-metal gauge of 1893 and its adoption by some manufacturers of sheet iron have only added to the existing confusion of gauges. A joint committee of the American Society of Mechanical Engineers and the American Railway Master Mechanics' Association in 1895 agreed to recommend the use of the decimal gauge, that is, a gauge whose number for each thickness is the number of thousandths of an inch in that thickness, and also to recommend "the abandonment and disuse of the various other gauges now in use, as tending to confusion and error." A notched gauge of oval form, shown in the cut below, has come into use as a standard form of the decimal gauge.

In 1904 The Westinghouse Electric & Mfg. Co. abandoned the use of gauge numbers in referring to wire, sheet metal, etc.

## ALGEBRA.

**Addition.**—Add  $a$  and  $b$ . Ans.  $a + b$ . Add  $a, b$ , and  $-c$ . Ans.  $a + b - c$ .  
Add  $2a$  and  $-3a$ . Ans.  $-a$ . Add  $2ab, -3ab, -c, -3c$ . Ans.  $-ab - 4c$ .

**Subtraction.**—Subtract  $a$  from  $b$ . Ans.  $b - a$ . Subtract  $-a$  from  $-b$ .  
Ans.  $-b + a$ .

Subtract  $b + c$  from  $a$ . Ans.  $a - b - c$ . Subtract  $3a^2b - 9c$  from  $4a^2b + c$ .  
Ans.  $a^2b + 10c$ . **RULE:** Change the signs of the subtrahend and proceed as  
in addition.

**Multiplication.**—Multiply  $a$  by  $b$ . Ans.  $ab$ . Multiply  $ab$  by  $a + b$ .  
Ans.  $a^2b + ab^2$ .

Multiply  $a + b$  by  $a + b$ . Ans.  $(a + b)(a + b) = a^2 + 2ab + b^2$ .

Multiply  $-a$  by  $-b$ . Ans.  $ab$ . Multiply  $-a$  by  $b$ . Ans.  $-ab$ . Like  
signs give plus, unlike signs minus.

**Powers of numbers.**—The product of two or more powers of any  
number is the number with an exponent equal to the sum of the powers:  
 $a^2 \times a^3 = a^5$ ;  $a^2b^2 \times ab = a^3b^3$ ;  $-7ab \times 2ac = -14a^2bc$ .

To multiply a polynomial by a monomial, multiply each term of the poly-  
nomial by the monomial and add the partial products:  $(6a - 3b) \times 3c = 18ac$   
 $- 9bc$ .

To multiply two polynomials, multiply each term of one factor by each  
term of the other and add the partial products:  $(5a - 6b) \times (3a - 4b) =$   
 $15a^2 - 38ab + 24b^2$ .

The square of the sum of two numbers = sum of their squares + twice  
their product.

The square of the difference of two numbers = the sum of their squares  
- twice their product.

The product of the sum and difference of two numbers = the difference  
of their squares:

$$(a + b)^2 = a^2 + 2ab + b^2; \quad (a - b)^2 = a^2 - 2ab + b^2;$$

$$(a + b) \times (a - b) = a^2 - b^2.$$

The square of half the sums of two quantities is equal to their product plus  
the square of half their difference:  $\left(\frac{a + b}{2}\right)^2 = ab + \left(\frac{a - b}{2}\right)^2$ .

The square of the sum of two quantities is equal to four times their prod-  
ucts, plus the square of their difference:  $(a + b)^2 = 4ab + (a - b)^2$

The sum of the squares of two quantities equals twice their product, plus  
the square of their difference:  $a^2 + b^2 = 2ab + (a - b)^2$ .

The square of a trinomial = the square of each term + twice the product  
of each term by each of the terms that follow it:  $(a + b + c)^2 = a^2 + b^2 +$   
 $c^2 + 2ab + 2ac + 2bc$ ;  $(a - b - c)^2 = a^2 + b^2 + c^2 - 2ab - 2ac + 2bc$ .

The square of (any number +  $\frac{1}{2}$ ) = square of the number + the number  
+  $\frac{1}{4}$ ; = the number  $\times$  (the number + 1) +  $\frac{1}{4}$ ;

$(a + \frac{1}{2})^2 = a^2 + a + \frac{1}{4}$ ,  $= a(a + 1) + \frac{1}{4}$ .  $(4\frac{1}{2})^2 = 4^2 + 4 + \frac{1}{4} = 4 \times 5 + \frac{1}{4} = 20\frac{1}{4}$ .

The product of any number +  $\frac{1}{2}$  by any other number +  $\frac{1}{2}$  = product of  
the numbers + half their sum +  $\frac{1}{4}$ .  $(a + \frac{1}{2}) \times (b + \frac{1}{2}) = ab + \frac{1}{2}(a + b) + \frac{1}{4}$ .

$4\frac{1}{2} \times 6\frac{1}{2} = 4 \times 6 + \frac{1}{2}(4 + 6) + \frac{1}{4} = 24 + 5 + \frac{1}{4} = 29\frac{1}{4}$ .

**Square, cube, 4th power, etc., of a binomial  $a + b$ .**

$$(a + b)^2 = a^2 + 2ab + b^2; \quad (a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3;$$

$$(a + b)^4 = a^4 + 4a^3b + 6a^2b^2 + 4ab^3 + b^4.$$

In each case the number of terms is one greater than the exponent of  
the power to which the binomial is raised.

2. In the first term the exponent of  $a$  is the same as the exponent of the  
power to which the binomial is raised, and it decreases by 1 in each succeed-  
ing term.

3.  $b$  appears in the second term with the exponent 1, and its exponent  
increases by 1 in each succeeding term.

4. The coefficient of the first term is 1.

5. The coefficient of the second term is the exponent of the power to  
which the binomial is raised.

6. The coefficient of each succeeding term is found from the next pre-  
ceding term by multiplying its coefficient by the exponent of  $a$ , and divid-  
ing the product by a number greater by 1 than the exponent of  $b$ . (See  
Binomial Theorem, below.)

**Parentheses.**—When a parenthesis is preceded by a plus sign it may be removed without changing the value of the expression:  $a + b + (a + b) = 2a + 2b$ . When a parenthesis is preceded by a minus sign it may be removed if we change the signs of all the terms within the parenthesis:  $1 - (a - b - c) = 1 - a + b + c$ . When a parenthesis is within a parenthesis remove the inner one first:  $a - \left[ b - \left\{ c - (d - e) \right\} \right] = a - \left[ b - \left\{ c - d + e \right\} \right] = a - [b - c + d - e] = a - b + c - d + e$ .

A multiplication sign,  $\times$ , has the effect of a parenthesis, in that the operation indicated by it must be performed before the operations of addition or subtraction.  $a + b \times a + b = a + ab + b$ ; while  $(a + b) \times (a + b) = a^2 + 2ab + b^2$ , and  $(a + b) \times a + b = a^2 + ab + b$ .

**Division.**—The quotient is positive when the dividend and divisor have like signs, and negative when they have unlike signs:  $abc \div b = ac$ ;  $abc \div -b = -ac$ .

To divide a monomial by a monomial, write the dividend over the divisor with a line between them. If the expressions have common factors, remove the common factors:

$$a^2bx \div aby = \frac{a^2bx}{aby} = \frac{ax}{y}; \quad \frac{a^4}{a^3} = a; \quad \frac{a^3}{a^5} = \frac{1}{a^2} = a^{-2}.$$

To divide a polynomial by a monomial, divide each term of the polynomial by the monomial:  $(8ab - 12ac) \div 4a = 2b - 3c$ .

To divide a polynomial by a polynomial, arrange both dividend and divisor in the order of the ascending or descending powers of some common letter, and keep this arrangement throughout the operation.

Divide the first term of the dividend by the first term of the divisor, and write the result as the first term of the quotient.

Multiply all the terms of the divisor by the first term of the quotient and subtract the product from the dividend. If there be a remainder, consider it as a new dividend and proceed as before:  $(a^2 - b^2) \div (a + b)$ .

$$\begin{array}{r} a^2 - b^2 \mid a + b. \\ \underline{a^2 + ab} \mid a - b. \\ \quad - ab - b^2. \\ \quad \underline{- ab - b^2.} \end{array}$$

The difference of two equal odd powers of any two numbers is divisible by their difference and also by their sum:

$$(a^3 - b^3) \div (a - b) = a^2 + ab + b^2; \quad (a^3 - b^3) \div (a + b) = a^2 - ab + b^2.$$

The difference of two equal even powers of two numbers is divisible by their difference and also by their sum:  $(a^2 - b^2) \div (a - b) = a + b$ .

The sum of two equal even powers of two numbers is not divisible by either the difference or the sum of the numbers; but when the exponent of each of the two equal powers is composed of an odd and an even factor, the sum of the given power is divisible by the sum of the powers expressed by the even factor. Thus  $x^6 + y^6$  is not divisible by  $x + y$  or by  $x - y$ , but is divisible by  $x^2 + y^2$ .

**Simple equations.**—An equation is a statement of equality between two expressions; as,  $a + b = c + d$ .

A simple equation, or equation of the first degree, is one which contains only the first power of the unknown quantity. If equal changes be made (by addition, subtraction, multiplication, or division) in both sides of an equation, the results will be equal.

Any term may be changed from one side of an equation to another, provided its sign be changed:  $a + b = c + d$ ;  $a = c + d - b$ . To solve an equation having one unknown quantity, transpose all the terms involving the unknown quantity to one side of the equation, and all the other terms to the other side; combine like terms, and divide both sides by the coefficient of the unknown quantity.

$$\text{Solve } 8x - 29 = 26 - 3x. \quad 8x + 3x = 29 + 26; \quad 11x = 55; \quad x = 5, \text{ ans.}$$

Simple algebraic problems containing one unknown quantity are solved by making  $x$  = the unknown quantity, and stating the conditions of the problem in the form of an algebraic equation, and then solving the equation. What two numbers are those whose sum is 48 and difference 14? Let  $x$  = the smaller number,  $x + 14$  the greater.  $x + x + 14 = 48$ .  $2x = 34$ ,  $x = 17$ ;  $x + 14 = 31$ , ans.

Find a number whose treble exceeds 50 as much as its double falls short of 40. Let  $x$  = the number.  $3x - 50 = 40 - 2x$ ;  $5x = 90$ ;  $x = 18$ , ans. Proving,  $54 - 50 = 40 - 36$ .

**Equations containing two unknown quantities.**—If one equation contains two unknown quantities,  $x$  and  $y$ , an indefinite number of pairs of values of  $x$  and  $y$  may be found that will satisfy the equation, but if a second equation be given only one pair of values can be found that will satisfy both equations. Simultaneous equations, or those that may be satisfied by the same values of the unknown quantities, are solved by combining the equations so as to obtain a single equation containing only one unknown quantity. This process is called elimination.

*Elimination by addition or subtraction.*—Multiply the equation by such numbers as will make the coefficients of one of the unknown quantities equal in the resulting equation. Add or subtract the resulting equations according as they have unlike or like signs.

$$\text{Solve } \begin{cases} 2x + 3y = 7. & \text{Multiply by 2: } 4x + 6y = 14 \\ 4x - 5y = 3. & \text{Subtract: } 4x - 5y = 3 \end{cases} \quad 11y = 11; y = 1.$$

Substituting value of  $y$  in first equation,  $2x + 3 = 7$ ;  $x = 2$ .

*Elimination by substitution.*—From one of the equations obtain the value of one of the unknown quantities in terms of the other. Substitute for this unknown quantity its value in the other equation and reduce the resulting equations.

$$\text{Solve } \begin{cases} 2x + 3y = 8. & (1). \text{ From (1) we find } x = \frac{8 - 3y}{2}. \\ 3x + 7y = 7. & (2). \end{cases}$$

Substitute this value in (2):  $3\left(\frac{8 - 3y}{2}\right) + 7y = 7$ ;  $= 24 - 9y + 14y = 14$ , whence  $y = -2$ . Substitute this value in (1):  $2x - 6 = 8$ ;  $x = 7$ .

*Elimination by comparison.*—From each equation obtain the value of one of the unknown quantities in terms of the other. Form an equation from these equal values, and reduce this equation.

$$\text{Solve } \begin{cases} 2x - 9y = 11. & (1). \text{ From (1) we find } x = \frac{11 + 9y}{2}. \\ 3x - 4y = 7. & (2). \text{ From (2) we find } x = \frac{7 + 4y}{3}. \end{cases}$$

Equating these values of  $x$ ,  $\frac{11 + 9y}{2} = \frac{7 + 4y}{3}$ ;  $19y = -19$ ;  $y = -1$ .

Substitute this value of  $y$  in (1):  $2x + 9 = 11$ ;  $x = 1$ .

If three simultaneous equations are given containing three unknown quantities, one of the unknown quantities must be eliminated between two pairs of the equations; then a second between the two resulting equations.

**Quadratic equations.**—A quadratic equation contains the square of the unknown quantity, but no higher power. A pure quadratic contains the square only; an affected quadratic both the square and the first power.

*To solve a pure quadratic,* collect the unknown quantities on one side, and the known quantities on the other; divide by the coefficient of the unknown quantity and extract the square root of each side of the resulting equation.

$$\text{Solve } 3x^2 - 15 = 0. \quad 3x^2 = 15; x^2 = 5; x = \sqrt{5}$$

A root like  $\sqrt{5}$ , which is indicated, but which can be found only approximately, is called a *surd*.

$$\text{Solve } 3x^2 + 15 = 0. \quad 3x^2 = -15; x^2 = -5; x = \sqrt{-5}.$$

The square root of  $-5$  cannot be found even approximately, for the square of any number positive or negative is positive; therefore a root which is indicated, but cannot be found even approximately, is called *imaginary*.

*To solve an affected quadratic.*—1. Convert the equation into the form  $a^2x^2 \pm 2abx = c$ , multiplying or dividing the equation if necessary, so as to make the coefficient of  $x^2$  a square number.

2. Complete the square of the first member of the equation, so as to convert it to the form of  $a^2x^2 \pm 2abx + b^2$ , which is the square of the binomial  $ax \pm b$ , as follows: add to each side of the equation the square of the quotient obtained by dividing the second term by twice the square root of the first term.

3. Extract the square root of each side of the resulting equation.

Solve  $3x^2 - 4x = 32$ . To make the coefficient of  $x^2$  a square number, multiply by 3:  $9x^2 - 12x = 96$ ;  $12x \div (2 \times 3x) = 2$ ;  $2^2 = 4$ .

Complete the square:  $9x^2 - 12x + 4 = 100$ . Extract the root:  $3x - 2 = \pm$

10, whence  $x = 4$  or  $-2 \frac{2}{3}$ . The square root of 100 is either  $+10$  or  $-10$ , since the square of  $-10$  as well as  $+10^2 = 100$ .

Problems involving quadratic equations have apparently two solutions, as a quadratic has two roots. Sometimes both will be true solutions, but generally one only will be a solution and the other be inconsistent with the conditions of the problem.

The sum of the squares of two consecutive positive numbers is 481. Find the numbers.

Let  $x =$  one number,  $x + 1$  the other.  $x^2 + (x + 1)^2 = 481$ .  $2x^2 + 2x + 1 = 481$ .

$x^2 + x = 240$ . Completing the square,  $x^2 + x + 0.25 = 240.25$ . Extracting the root we obtain  $x + 0.5 = \pm 15.5$ ;  $x = 15$  or  $-16$ .

The positive root gives for the numbers 15 and 16. The negative root  $-16$  is inconsistent with the conditions of the problem.

Quadratic equations containing two unknown quantities require different methods for their solution, according to the form of the equations. For these methods reference must be made to works on algebra.

**Theory of exponents.**— $\sqrt[n]{a}$  when  $n$  is a positive integer is one of  $n$  equal factors of  $a$ .  $\sqrt[n]{a^m}$  means  $a$  is to be raised to the  $m$ th power and the  $n$ th root extracted.

$(\sqrt[n]{a})^m$  means that the  $n$ th root of  $a$  is to be taken and the result raised to the  $m$ th power.

$\sqrt[n]{a^m} = (\sqrt[n]{a})^m = a^{\frac{m}{n}}$ . When the exponent is a fraction, the numerator indicates a power, and the denominator a root.  $a^{\frac{6}{2}} = \sqrt{a^6} = a^3$ ;  $a^{\frac{3}{2}} = \sqrt{a^3} = a^{1.5}$ .

To extract the root of a quantity raised to an indicated power, divide the exponent by the index of the required root; as,

$$\sqrt[n]{a^m} = a^{\frac{m}{n}}; \quad \sqrt[3]{a^6} = a^{\frac{6}{3}} = a^2.$$

Subtracting 1 from the exponent of  $a$  is equivalent to dividing by  $a$ :

$$a^2 - 1 = a^1 = a; \quad a^1 - 1 = a^0 = \frac{a}{a} = 1; \quad a^0 - 1 = a^{-1} = \frac{1}{a}; \quad a^{-1} - 1 = a^{-2} = \frac{1}{a^2}$$

A number with a negative exponent denotes the reciprocal of the number with the corresponding positive exponent.

A factor under the radical sign whose root can be taken may, by having the root taken, be removed from under the radical sign:

$$\sqrt{a^2 b} = \sqrt{a^2} \times \sqrt{b} = a \sqrt{b}.$$

A factor outside the radical sign may be raised to the corresponding power and placed under it:

$$\sqrt{\frac{a}{b}} = \sqrt{\frac{ab}{b^2}} = \sqrt{ab \times \frac{1}{b^2}} = \frac{1}{b} \sqrt{ab}; \quad \sqrt{\frac{a}{b^2}} = \frac{1}{b} \sqrt{a}$$

**Binomial Theorem.**—To obtain any power, as the  $n$ th, of an expression of the form  $x + a$

$$(a + x)^n = a^n + na^{n-1}x + \frac{n(n-1)a^{n-2}}{1.2}x^2 + \frac{n(n-1)(n-2)a^{n-3}}{1.2.3}x^3 + \text{etc.}$$

The following laws hold for any term in the expansion of  $(a + x)^n$ .

The exponent of  $x$  is less by one than the number of terms.

The exponent of  $a$  is  $n$  minus the exponent of  $x$ .

The last factor of the numerator is greater by one than the exponent of  $a$ .

The last factor of the denominator is the same as the exponent of  $x$ .

In the  $r$ th term the exponent of  $x$  will be  $r - 1$ .

The exponent of  $a$  will be  $n - (r - 1)$ , or  $n - r + 1$ .

The last factor of the numerator will be  $n - r + 2$ .

The last factor of the denominator will be  $r - 1$ .

Hence the  $r$ th term =  $\frac{n(n-1)(n-2) \dots (n-r+2)}{1.2.3 \dots (r-1)} a^{n-r+1} x^{r-1}$

GEOMETRICAL PROBLEMS.

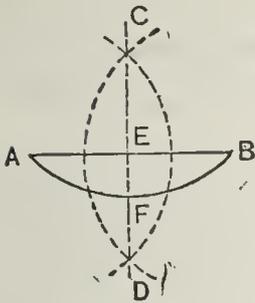

FIG. 1.

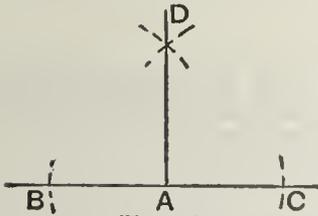

FIG. 2.

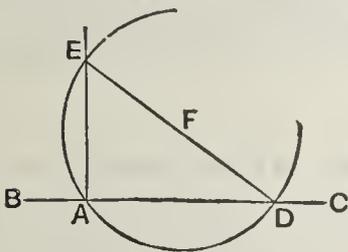

FIG. 3.

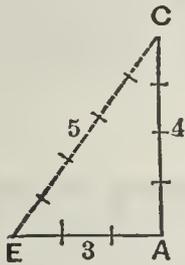

FIG. 4.

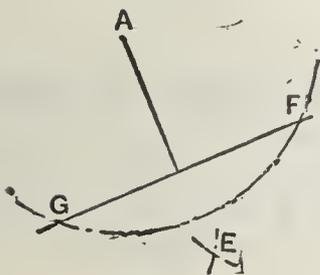

FIG. 5.

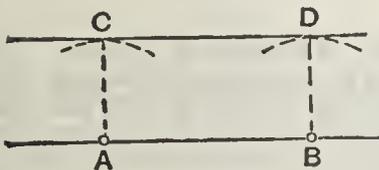

FIG. 6.

**1. To bisect a straight line, or an arc of a circle** (Fig. 1).—From the ends  $A, B$ , as centres, describe arcs intersecting at  $C$  and  $D$ , and draw a line through  $C$  and  $D$  which will bisect the line at  $E$  or the arc at  $F$ .

**2. To draw a perpendicular to a straight line, or a radial line to a circular arc.**—Same as in Problem 1.  $CD$  is perpendicular to the line  $AB$ , and also radial to the arc.

**3. To draw a perpendicular to a straight line from a given point in that line** (Fig. 2).—With any radius, from the given point  $A$  in the line  $BC$ , cut the line at  $B$  and  $C$ . With a longer radius describe arcs from  $B$  and  $C$ , cutting each other at  $D$ , and draw the perpendicular  $DA$ .

**4. From the end  $A$  of a given line  $AD$  to erect a perpendicular  $AE$**  (Fig. 3).—From any centre  $F$ , above  $AD$ , describe a circle passing through the given point  $A$ , and cutting the given line at  $D$ . Draw  $DF$  and produce it to cut the circle at  $E$ , and draw the perpendicular  $AE$ .

*Second Method* (Fig. 4).—From the given point  $A$  set off a distance  $AE$  equal to three parts, by any scale; and on the centres  $A$  and  $E$ , with radii of four and five parts respectively, describe arcs intersecting at  $C$ . Draw the perpendicular  $AC$ .

NOTE.—This method is most useful on very large scales, where straight edges are inapplicable. Any multiples of the numbers 3, 4, 5 may be taken with the same effect as 6, 8, 10, or 9, 12, 15.

**5. To draw a perpendicular to a straight line from any point without it** (Fig. 5).—From the point  $A$ , with a sufficient radius cut the given line at  $F$  and  $G$ , and from these points describe arcs cutting at  $E$ . Draw the perpendicular  $AE$ .

**6. To draw a straight line parallel to a given line, at a given distance apart** (Fig. 6).—From the centres  $A, B$ , in the given line, with the given distance as radius, describe arcs  $C, D$ , and draw the parallel lines  $CD$  touching the arcs.

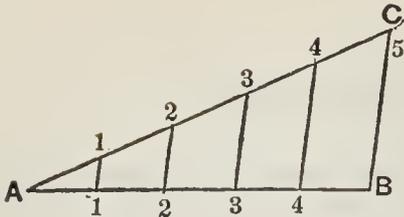

FIG. 7.

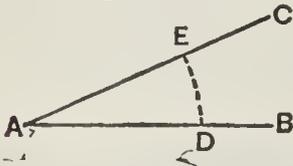

FIG. 8.

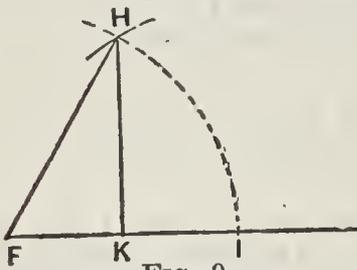

FIG. 9.

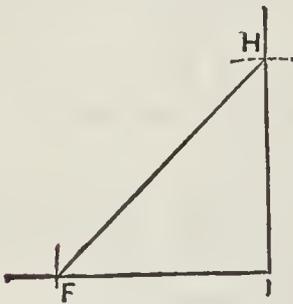

FIG. 10.

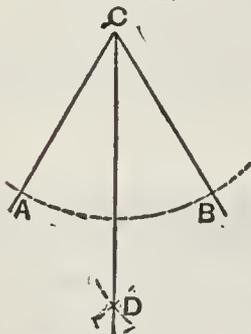

FIG. 11.

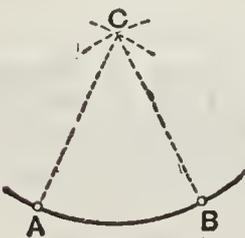

FIG. 12.

**7. To divide a straight line into a number of equal parts** (Fig. 7).—To divide the line  $AB$  into, say, five parts, draw the line  $AC$  at an angle from  $A$ ; set off five equal parts; draw  $B5$  and draw parallels to it from the other points of division in  $AC$ . These parallels divide  $AB$  as required.

**NOTE.**—By a similar process a line may be divided into a number of unequal parts; setting off divisions on  $AC$ , proportional by a scale to the required divisions, and drawing parallel cutting  $AB$ . The triangles  $A11$ ,  $A22$ ,  $A33$ , etc., are *similar triangles*.

**8. Upon a straight line to draw an angle equal to a given angle** (Fig. 8).—Let  $A$  be the given angle and  $F'G$  the line. From the point  $A$  with any radius describe the arc  $DE$ . From  $F$  with the same radius describe  $I'H$ . Set off the arc  $I'H$  equal to  $DE$ , and draw  $F'H$ . The angle  $F$  is equal to  $A$ , as required.

**9. To draw angles of  $60^\circ$  and  $30^\circ$**  (Fig. 9).—From  $F$ , with any radius  $FI$ , describe an arc  $I'H$ ; and from  $I$ , with the same radius, cut the arc at  $H$  and draw  $F'H$  to form the required angle  $I'F'H$ . Draw the perpendicular  $H'K$  to the base line to form the angle of  $30^\circ F'H'K$ .

**10. To draw an angle of  $45^\circ$**  (Fig. 10).—Set off the distance  $FI$ ; draw the perpendicular  $I'H$  equal to  $I'F$ , and join  $H'F$  to form the angle at  $F$ . The angle at  $H$  is also  $45^\circ$ .

**11. To bisect an angle** (Fig. 11).—Let  $ACB$  be the angle; with  $C$  as a centre draw an arc cutting the sides at  $A, B$ . From  $A$  and  $B$  as centres, describe arcs cutting each other at  $D$ . Draw  $CD$ , dividing the angle into two equal parts.

**12. Through two given points to describe an arc of a circle with a given radius** (Fig. 12).—From the points  $A$  and  $B$  as centres, with the given radius, describe arcs cutting at  $C$ ; and from  $C$  with the same radius describe an arc  $AB$ .

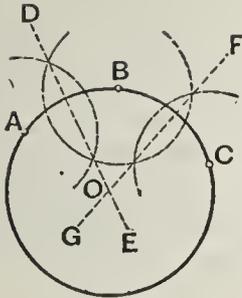

FIG. 13.

**13. To find the centre of a circle or of an arc of a circle** (Fig. 13).—Select three points,  $A, B, C$ , in the circumference, well apart; with the same radius describe arcs from these three points, cutting each other, and draw the two lines,  $DE, FG$ , through their intersections. The point  $O$ , where they cut, is the centre of the circle or arc.

**To describe a circle passing through three given points.**—Let  $A, B, C$  be the given points, and proceed as in last problem to find the centre  $O$ , from which the circle may be described.

**14. To describe an arc of a circle passing through three given points when the centre is not available** (Fig. 14).—From the extreme points  $A, B$ , as centres, describe arcs  $AH, BG$ . Through the third point  $C$  draw  $AE, BF$ , cutting the arcs. Divide  $AF$  and  $BE$  into any number of equal parts, and set off a series of equal parts of the same length on the upper portions of the arcs beyond the points  $EF$ . Draw straight lines,  $BL, BM$ , etc., to the divisions in  $AF$ , and  $AI, AK$ , etc., to the divisions in  $BE$ . The successive intersections  $N, O$ , etc., of these lines are points in the circle required between the given points  $A$  and  $C$ , which may be drawn in; similarly the remaining part of the curve  $BC$  may be described. (See also Problem 54.)

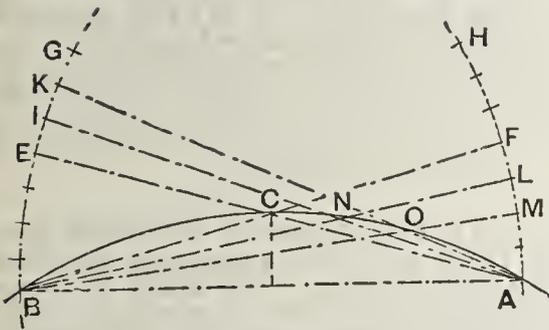

FIG. 14.

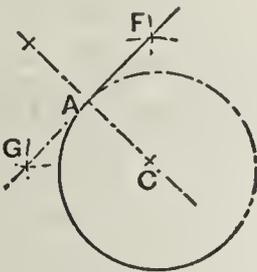

FIG. 15.

**15. To draw a tangent to a circle from a given point in the circumference** (Fig. 15).—Through the given point  $A$ , draw the radial line  $AC$ , and a perpendicular to it,  $FG$ , which is the tangent required.

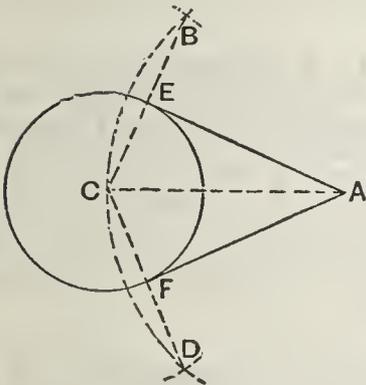

FIG. 16.

**16. To draw tangents to a circle from a point without it** (Fig. 16).—From  $A$ , with the radius  $AC$ , describe an arc  $BCD$ , and from  $C$ , with a radius equal to the diameter of the circle, cut the arc at  $B, D$ . Join  $BC, CD$ , cutting the circle at  $E, F$ , and draw  $AE, AF$ , the tangents.

NOTE.—When a tangent is already drawn, the exact point of contact may be found by drawing a perpendicular to it from the centre.

**17. Between two inclined lines to draw a series of circles touching these lines and touching each other** (Fig. 17).—Bisect the inclination of the given lines  $AB, CD$ , by the line  $NO$ . From a point  $P$  in this line draw the perpendicular  $PB$  to the line  $AB$ , and

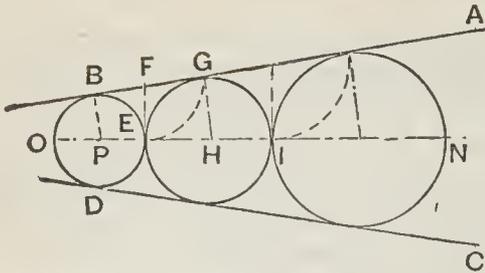

FIG. 17.

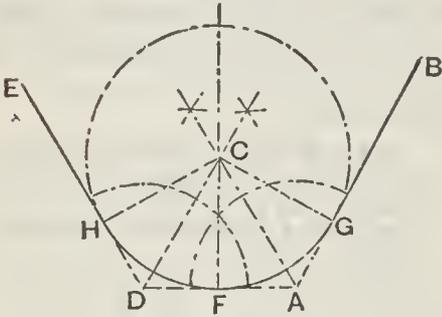

FIG. 18.

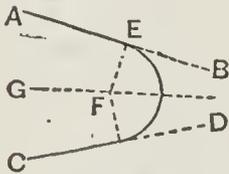

FIG. 19.

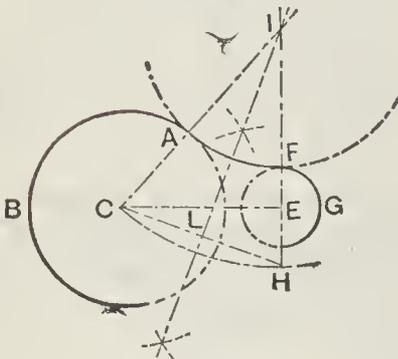

FIG. 20.

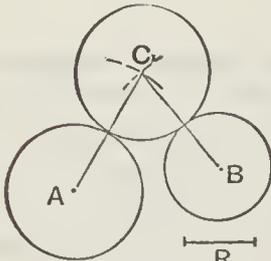

FIG. 21.

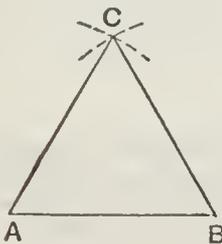

FIG. 22.

on  $P$  describe the circle  $BD$ , touching the lines and cutting the centre line at  $E$ . From  $E$  draw  $EF$  perpendicular to the centre line, cutting  $AB$  at  $F$ , and from  $F$  describe an arc  $EG$ , cutting  $AB$  at  $G$ . Draw  $GH$  parallel to  $BP$ , giving  $H$ , the centre of the next circle, to be described with the radius  $HE$ , and so on for the next circle  $IN$ .

Inversely, the largest circle may be described first, and the smaller ones in succession. This problem is of frequent use in scroll-work.

**18. Between two inclined lines to draw a circular segment tangent to the lines and passing through a point  $F$  on the line  $FC$  which bisects the angle of the lines** (Fig. 18).

—Through  $F$  draw  $DA$  at right angles to  $FC$ ; bisect the angles  $A$  and  $D$ , as in Problem 11, by lines cutting at  $C$ , and from  $C$  with radius  $CF$  draw the arc  $HFG$  required.

**19. To draw a circular arc that will be tangent to two given lines  $AB$  and  $CD$  inclined to one another, one tangential point  $E$  being given** (Fig. 19).

—Draw the centre line  $GF$ . From  $E$  draw  $EF$  at right to angles  $AB$ ; then  $F$  is the centre of the circle required.

**20. To describe a circular arc joining two circles, and touching one of them at a given point** (Fig. 20).—To join the circles  $AB, FG$ , by an arc touching one of them at  $F$ , draw the radius  $EF$ , and produce it both ways. Set off  $FH$  equal to the radius  $AC$  of the other circle; join  $CH$  and bisect it with the perpendicular  $LI$ , cutting  $EF$  at  $I$ . On the centre  $I$ , with radius  $IF$ , describe the arc  $FA$  as required.

**21. To draw a circle with a given radius  $R$  that will be tangent to two given circles  $A$  and  $B$**  (Fig. 21).

—From centre of circle  $A$  with radius equal  $R$  plus radius of  $A$ , and from centre of  $B$  with radius equal to  $R +$  radius of  $B$ , draw two arcs cutting each other in  $C$ , which will be the centre of the circle required.

**22. To construct an equilateral triangle, the sides being given** (Fig. 22).

—On the ends of one side,  $A, B$ , with  $AB$  as radius, describe arcs cutting at  $C$ , and draw  $AC, CB$ .

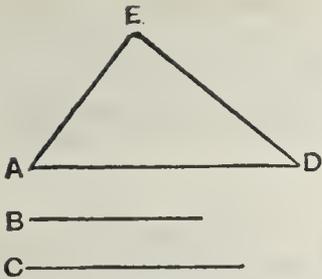

FIG. 23.

**23. To construct a triangle of unequal sides** (Fig. 23).—On either end of the base  $AD$ , with the side  $B$  as radius, describe an arc; and with the side  $C$  as radius, on the other end of the base as a centre, cut the arc at  $E$ . Join  $AE$ ,  $DE$ .

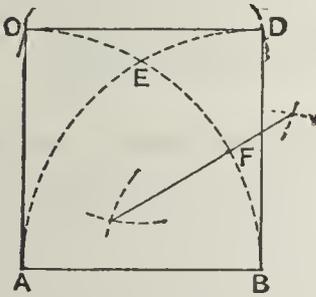

FIG. 24.

**24. To construct a square on a given straight line  $AB$**  (Fig. 24).—With  $AB$  as radius and  $A$  and  $B$  as centres, draw arcs  $AD$  and  $BC$ , intersecting at  $E$ . Bisect  $EB$  at  $F$ . With  $E$  as centre and  $EF$  as radius, cut the arcs  $AD$  and  $BC$  in  $D$  and  $C$ . Join  $AC$ ,  $CD$ , and  $DB$  to form the square.

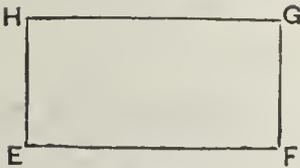

FIG. 25.

**25. To construct a rectangle with given base  $EF$  and height  $EH$**  (Fig. 25).—On the base  $EF$  draw the perpendiculars  $EH$ ,  $FG$  equal to the height, and join  $GH$ .

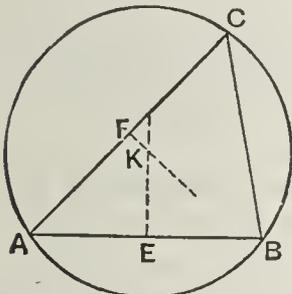

FIG. 26.

**26. To describe a circle about a triangle** (Fig. 26).—Bisect two sides  $AB$ ,  $AC$  of the triangle at  $E$ ,  $F$ , and from these points draw perpendiculars cutting at  $K$ . On the centre  $K$ , with the radius  $KA$ , draw the circle  $ABC$ .

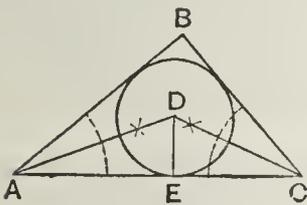

FIG. 27.

**27. To inscribe a circle in a triangle** (Fig. 27).—Bisect two of the angles  $A$ ,  $C$ , of the triangle by lines cutting at  $D$ ; from  $D$  draw a perpendicular  $DE$  to any side, and with  $DE$  as radius describe a circle.

When the triangle is equilateral, draw a perpendicular from one of the angles to the opposite side, and from the side set off one third of the perpendicular.

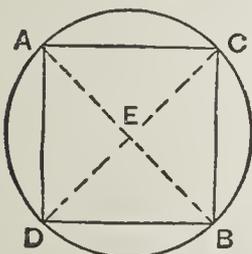

FIG. 28.

**28. To describe a circle about a square, and to inscribe a square in a circle** (Fig. 28).—To describe the circle, draw the diagonals  $AB$ ,  $CD$  of the square, cutting at  $E$ . On the centre  $E$ , with the radius  $AE$ , describe the circle.

**To inscribe the square.**—Draw the two diameters,  $AB$ ,  $CD$ , at right angles, and join the points  $A$ ,  $B$ ,  $C$ ,  $D$ , to form the square.

NOTE.—In the same way a circle may be described about a rectangle.

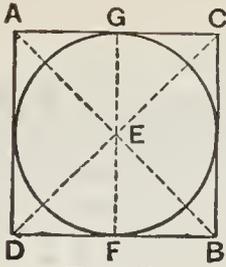

FIG. 29.

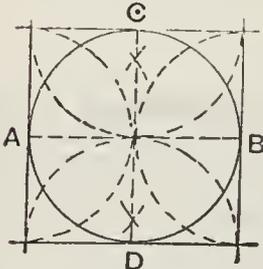

FIG. 30.

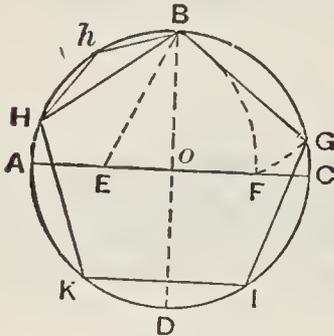

FIG. 31.

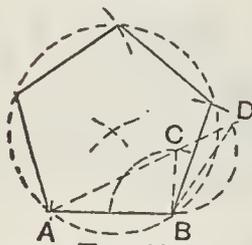

FIG. 32.

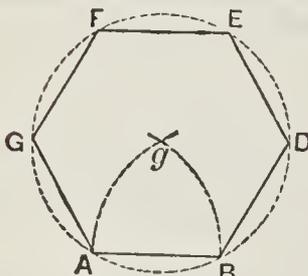

FIG. 33.

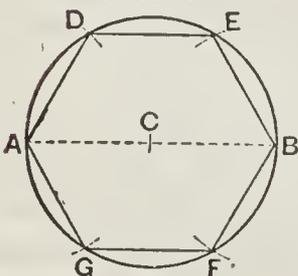

FIG. 34.

**29. To inscribe a circle in a square** (Fig. 29).—To inscribe the circle, draw the diagonals  $AB$ ,  $CD$  of the square, cutting at  $E$ ; draw the perpendicular  $EF$  to one side, and with the radius  $EF$  describe the circle.

**30. To describe a square about a circle** (Fig. 30).—Draw two diameters  $AB$ ,  $CD$  at right angles. With the radius of the circle and  $A$ ,  $B$ ,  $C$  and  $D$  as centres, draw the four half circles which cross one another in the corners of the square.

**31. To inscribe a pentagon in a circle** (Fig. 31).—Draw diameters  $AC$ ,  $BD$  at right angles, cutting at  $o$ . Bisect  $AO$  at  $E$ , and from  $E$ , with radius  $EB$ , cut  $AC$  at  $F$ ; from  $B$ , with radius  $BF$ , cut the circumference at  $G$ ,  $H$ , and with the same radius step round the circle to  $I$  and  $K$ ; join the points so found to form the pentagon.

**32. To construct a pentagon on a given line  $AB$**  (Fig. 32).—From  $B$  erect a perpendicular  $BC$  half the length of  $AB$ ; join  $AC$  and prolong it to  $D$ , making  $CD = BC$ . Then  $BD$  is the radius of the circle circumscribing the pentagon. From  $A$  and  $B$  as centres, with  $BD$  as radius, draw arcs cutting each other in  $O$ , which is the centre of the circle.

**33. To construct a hexagon upon a given straight line** (Fig. 33).—From  $A$  and  $B$ , the ends of the given line, with radius  $AB$ , describe arcs cutting at  $g$ ; from  $g$ , with the radius  $gA$ , describe a circle; with the same radius set off the arcs  $AG$ ,  $GF$ , and  $BD$ ,  $DE$ . Join the points so found to form the hexagon. The side of a hexagon = radius of its circumscribed circle.

**34. To inscribe a hexagon in a circle** (Fig. 34).—Draw a diameter  $ACB$ . From  $A$  and  $B$  as centres, with the radius of the circle  $AC$ , cut the circumference at  $D$ ,  $E$ ,  $F$ ,  $G$ , and draw  $AD$ ,  $DE$ , etc., to form the hexagon. The radius of the circle is equal to the side of the hexagon; therefore the points  $D$ ,  $E$ , etc., may also be found by stepping the radius six times round the circle. The angle between the diameter and the sides of a hexagon and also the exterior angle between a side and an adjacent side prolonged is 60 degrees; therefore a hexagon may conveniently be drawn by the use of a 60-degree triangle.

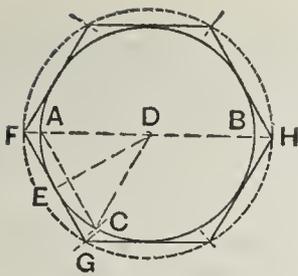

FIG. 35.

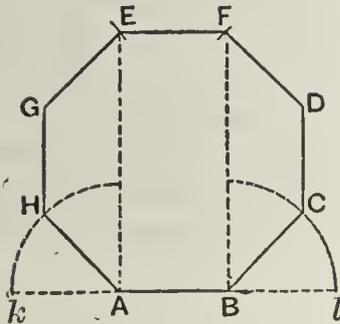

FIG. 36.

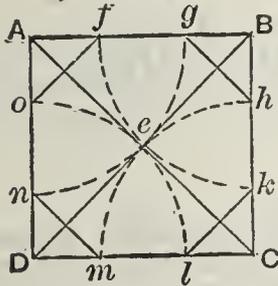

FIG. 37.

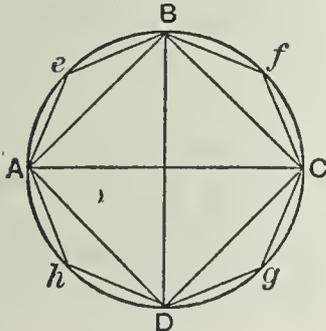

FIG. 38.

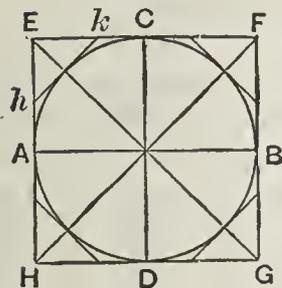

FIG. 39.

**35. To describe a hexagon about a circle** (Fig. 35).—Draw a diameter  $A D B$ , and with the radius  $A D$ , on the centre  $A$ , cut the circumference at  $C$ ; join  $A C$ , and bisect it with the radius  $D E$ ; through  $E$  draw  $F G$ , parallel to  $A C$ , cutting the diameter at  $F$ , and with the radius  $D F$  describe the circumscribing circle  $F H$ . Within this circle describe a hexagon by the preceding problem. A more convenient method is by use of a 60-degree triangle. Four of the sides make angles of 60 degrees with the diameter, and the other two are parallel to the diameter.

**36. To describe an octagon on a given straight line** (Fig. 36).—Produce the given line  $A B$  both ways, and draw perpendiculars  $A E$ ,  $B F$ ; bisect the external angles  $A$  and  $B$  by the lines  $A H$ ,  $B C$ , which make equal to  $A B$ . Draw  $C D$  and  $H G$  parallel to  $A E$ , and equal to  $A B$ ; from the centres  $G$ ,  $D$ , with the radius  $A B$ , cut the perpendiculars at  $E$ ,  $F$ , and draw  $E F$  to complete the octagon.

**37. To convert a square into an octagon** (Fig. 37).—Draw the diagonals of the square cutting at  $e$ ; from the corners  $A$ ,  $B$ ,  $C$ ,  $D$ , with  $A e$  as radius, describe arcs cutting the sides at  $g n$ ,  $f k$ ,  $h m$ , and  $o l$ , and join the points so found to form the octagon. Adjacent sides of an octagon make an angle of 135 degrees.

**38. To inscribe an octagon in a circle** (Fig. 38).—Draw two diameters,  $A C$ ,  $B D$  at right angles; bisect the arcs  $A B$ ,  $B C$ , etc., at  $e f$ , etc., and join  $A e$ ,  $e B$ , etc., to form the octagon.

**39. To describe an octagon about a circle** (Fig. 39).—Describe a square about the given circle  $A B$ ; draw perpendiculars  $h k$ , etc., to the diagonals, touching the circle to form the octagon.

**40. To describe a polygon of any number of sides upon a given straight line** (Fig. 40).—Produce the given line  $A B$ , and on  $A$ ,

In this table the angle at the centre is found by dividing 360 degrees, the number of degrees in a circle, by the number of sides in the polygon; and by setting off round the centre of the circle a succession of angles by means of the protractor, equal to the angle in the table due to a given number of sides, the radii so drawn will divide the circumference into the same number of parts.

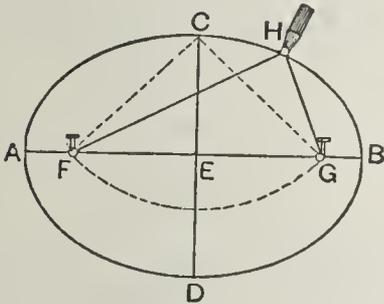

FIG. 44.

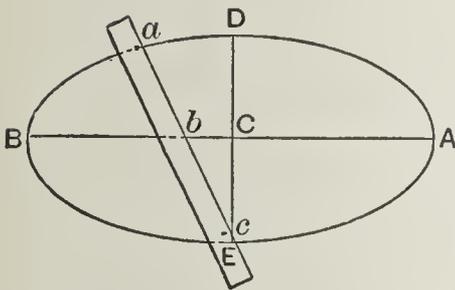

FIG. 45.

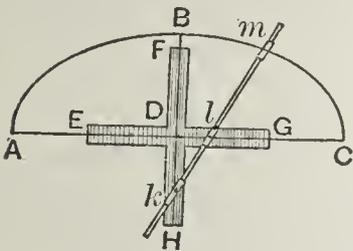

FIG. 46.

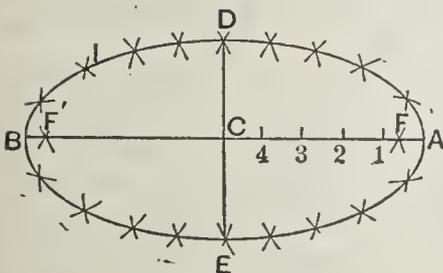

FIG. 47.

**44. To describe an ellipse when the length and breadth are given** (Fig. 44).— $AB$ , transverse axis;  $CD$ , conjugate axis;  $F G$ , foci. The sum of the distances from  $C$  to  $F$  and  $G$ , also the sum of the distances from  $F$  and  $G$  to any other point in the curve, is equal to the transverse axis. From the centre  $C$ , with  $AE$  as radius, cut the axis  $AB$  at  $F$  and  $G$ , the foci; fix a couple of pins into the axis at  $F$  and  $G$ , and loop on a thread or cord upon them equal in length to the axis  $AB$ , so as when stretched to reach to the extremity  $C$  of the conjugate axis, as shown in dot-lining. Place a pencil inside the cord as at  $H$ , and guiding the pencil in this way, keeping the cord equally in tension, carry the pencil round the pins  $F, G$ , and so describe the ellipse.

NOTE.—This method is employed in setting off elliptical garden-plots, walks, etc.

*2d Method* (Fig. 45).—Along the straight edge of a slip of stiff paper mark off a distance  $ac$  equal to  $AC$ , half the transverse axis; and from the same point a distance  $ab$  equal to  $CD$ , half the conjugate axis. Place the slip so as to bring the point  $b$  on the line  $AB$  of the transverse axis, and the point  $c$  on the line  $DE$ ; and set off on the drawing the position of the point  $a$ . Shifting the slip so that the point  $b$  travels on the transverse axis, and the point  $c$  on the conjugate axis, any number of points in the curve may be found, through which the curve may be traced.

*3d Method* (Fig. 46).—The action of the preceding method may be embodied so as to afford the means of describing a large curve continuously by means of a bar  $mk$ , with steel points  $m, l, k$ , riveted into brass slides adjusted to the length of the semi-axis and fixed with set-screws. A rectangular cross  $EG$ , with guiding-slots is placed, coinciding with the two axes of the ellipse  $AC$  and  $BH$ . By sliding the points  $k, l$  in the slots, and carrying round the point  $m$ , the curve may be continuously described. A pen or pencil may be fixed at  $m$ .

*4th Method* (Fig. 47).—Bisect the transverse axis at  $C$ , and through  $C$  draw the perpendicular  $DE$ , making  $CD$  and  $CE$  each equal to half the conjugate axis. From  $D$  or  $E$ , with the radius  $AC$ , cut the transverse axis at  $F, F'$ , for the foci. Divide  $AC$  into a number of parts at the

points 1, 2, 3, etc. With the radius  $A I$  on  $F$  and  $F'$  as centres, describe arcs, and with the radius  $B I$  on the same centres cut these arcs as shown.

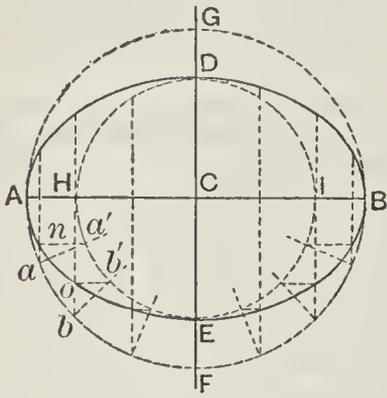

FIG. 48.

Repeat the operation for the other divisions of the transverse axis. The series of intersections thus made are points in the curve, through which the curve may be traced.

**5th Method** (Fig. 48).—On the two axes  $A B, D E$  as diameters, on centre  $C$ , describe circles; from a number of points  $a, b$ , etc., in the circumference  $A F B$ , draw radii cutting the inner circle at  $a', b'$ , etc. From  $a, b$ , etc., draw perpendiculars to  $A B$ ; and from  $a', b'$ , etc., draw parallels to  $A B$ , cutting the respective perpendiculars at  $n, o$ , etc. The intersections are points in the curve, through which the curve may be traced.

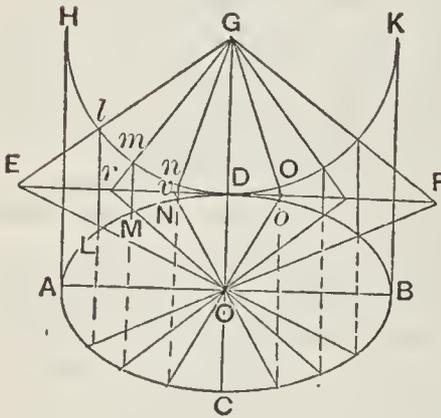

FIG. 49.

**6th Method** (Fig. 49).—When the transverse and conjugate diameters are given,  $A B, C D$ , draw the tangent  $E F$  parallel to  $A B$ . Produce  $C D$ , and on the centre  $G$  with the radius of half  $A B$ , describe a semicircle  $H D K$ ; from the centre  $G$  draw any number of straight lines to the points  $E, r$ , etc., in the line  $E F$ , cutting the circumference at  $l, m, n$ , etc.; from the centre  $O$  of the ellipse draw straight lines to the points  $E, r$ , etc.; and from the points  $l, m, n$ , etc., draw parallels to  $G C$ , cutting the lines  $O E, O r$ , etc., at  $L, M, N$ , etc. These are points in the circumference of the ellipse, and the curve may be traced through them. Points in the other half of the ellipse are formed by extending the intersecting lines as indicated in the figure.

**45. To describe an ellipse approximately by means of circular arcs.**—*First.*—With arcs of two radii (Fig. 50).—Find the difference of the semi-axes, and set it off from the centre  $O$  to  $a$  and  $c$  on  $O A$  and  $O C$ ; draw  $a c$ , and set off half  $a c$  to  $d$ ; draw  $d i$  parallel to  $a c$ ; set off  $O e$  equal to  $O d$ ; join  $e i$ , and draw the parallels  $e m, d m$ . From  $m$ , with radius  $m C$ , describe an arc through  $C$ ; and from  $i$  describe an arc through  $D$ ; from  $d$  and  $e$  describe arcs through  $A$  and  $B$ . The four arcs form the ellipse approximately.

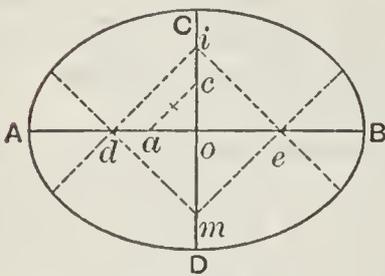

FIG. 50.

**NOTE.**—This method does not apply satisfactorily when the conjugate axis is less than two thirds of the transverse axis.

**2d Method** (by Carl G. Barth, Fig. 51).—In Fig. 51  $a b$  is the major and  $c d$  the minor axis of the ellipse to be approximated. Lay off  $b e$  equal to the semi-minor axis  $c O$ , and use  $a e$  as radius for the arc at each extremity of the minor axis. Bisect  $e o$  at  $f$  and lay off  $e g$  equal to  $e f$ , and use  $g b$  as radius for the arc at each extremity of the major axis.

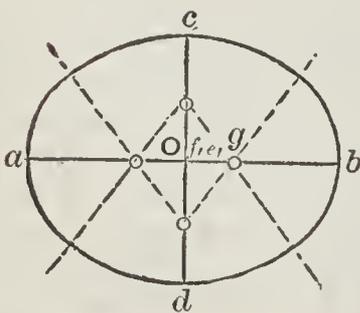

FIG. 51.

The method is not considered applicable for cases in which the minor axis is less than two thirds of the major.

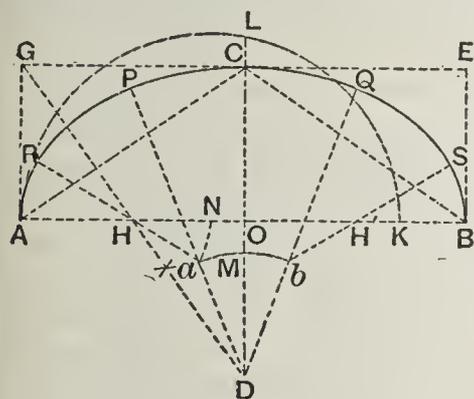

FIG. 52.

**3d Method:** With arcs of three radii (Fig. 52).—On the transverse axis  $AB$  draw the rectangle  $BG$  on the height  $OC$ ; to the diagonal  $AC$  draw the perpendicular  $GH$ ; set off  $OK$  equal to  $OC$ , and describe a semi-circle on  $AK$ , and produce  $OC$  to  $L$ ; set off  $OM$  equal to  $CL$ , and from  $D$  describe an arc with radius  $DM$ ; from  $A$ , with radius  $OL$ , cut  $AB$  at  $N$ ; from  $H$ , with radius  $HN$ , cut arc  $ab$  at  $a$ . Thus the five centres  $D, a, b, H, H'$  are found, from which the arcs are described to form the ellipse.

This process works well for nearly all proportions of ellipses. It is used in striking out vaults and stone bridges.

**4th Method** (by F. R. Honey, Figs. 53 and 54).—Three radii are employed. With the shortest radii describe the two arcs which pass through the vertices of the major axis, with the longest the two arcs which pass through the vertices of the minor axis, and with the third radius the four arcs which connect the former.

A simple method of determining the radii of curvature is illustrated in

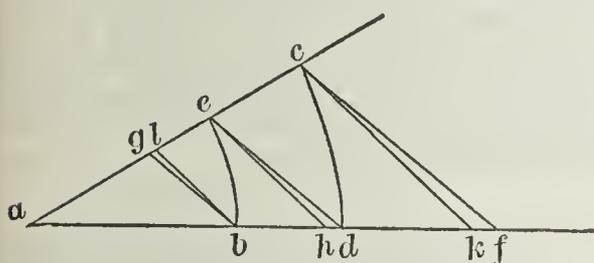

FIG. 53.

Fig. 53. Draw the straight lines  $af$  and  $ac$ , forming any angle at  $a$ . With  $a$  as a centre, and with radii  $ab$  and  $ac$ , respectively, equal to the semi-minor and semi-major axes, draw the arcs  $be$  and  $cd$ . Join  $ed$ , and through  $b$  and  $c$  respectively draw  $bg$  and  $cf$  parallel to  $ed$ , intersecting  $ac$  at  $g$ , and  $af$  at  $f$ ;  $af$  is the radius of curvature at the vertex of the minor axis; and  $ag$  the radius of curvature at the

vertex of the major axis.

Lay off  $dh$  (Fig. 53) equal to one eighth of  $bd$ . Join  $eh$ , and draw  $ck$  and  $bl$  parallel to  $eh$ . Take  $ak$  for the longest radius ( $= R$ ),  $al$  for the shortest radius ( $= r$ ), and the arithmetical mean, or one half the sum of the semi-axes, for the third radius ( $= p$ ), and employ these radii for the eight-centred oval as follows:

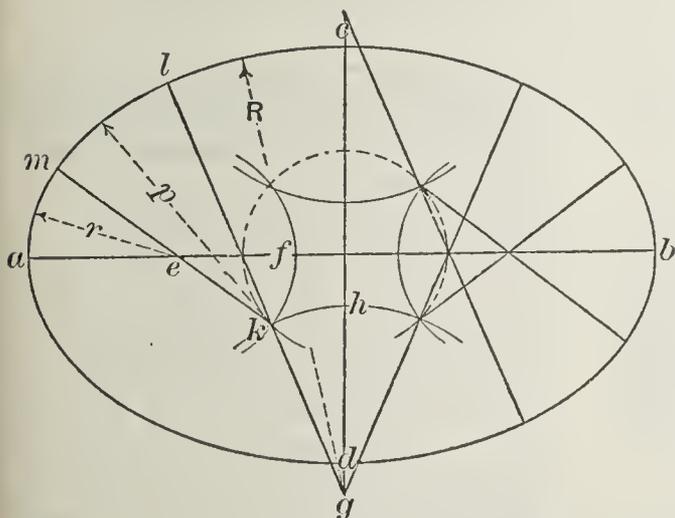

FIG. 54.

Let  $ab$  and  $cd$  (Fig. 54) be the major and minor axes. Lay off  $ae$  equal to  $r$ , and  $af$  equal to  $p$ ; also lay off  $cg$  equal to  $R$ , and  $ch$  equal to  $p$ . With  $g$  as a centre and  $gh$  as a radius, draw the arc  $hk$ ; with the centre  $e$  and radius  $ef$  draw the arc  $fk$ , intersecting  $hk$  at  $k$ . Draw the line  $gk$  and produce it, making  $gl$  equal to  $R$ . Draw  $ke$  and produce it, making  $km$  equal to  $p$ . With the centre  $g$  and radius  $gc$  ( $= R$ ) draw the arc  $cl$ ; with the centre  $k$  and radius  $kl$  ( $= p$ ) draw the arc  $lm$ , and with the centre  $e$  and radius  $em$  ( $= r$ ) draw the arc  $ma$ .

The remainder of the work is symmetrical with respect to the axes.

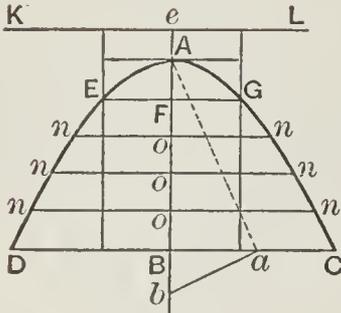

FIG. 55.

**46. The Parabola.**—A parabola ( $DAC$ , Fig. 55) is a curve such that every point in the curve is equally distant from the directrix  $KL$  and the focus  $F$ . The focus lies in the axis  $AB$  drawn from the vertex or head of the curve  $A$ , so as to divide the figure into two equal parts. The vertex  $A$  is equidistant from the directrix and the focus, or  $Ae = AF$ . Any line parallel to the axis is a diameter. A straight line, as  $EG$  or  $DC$ , drawn across the figure at right angles to the axis is a double ordinate, and either half of it is an ordinate. The ordinate to the axis  $EF$ , drawn through the focus, is called the parameter of the axis. A segment of the axis, reckoned from the vertex, is an abscissa of the axis, and it is an abscissa of the ordinate drawn from the base of the abscissa. Thus,  $AB$  is an abscissa of the ordinate  $BC$ .

Abscissæ of a parabola are as the squares of their ordinates.

**To describe a parabola when an abscissa and its ordinate are given** (Fig. 55).—Bisect the given ordinate  $BC$  at  $a$ , draw  $Aa$ , and then  $ab$  perpendicular to it, meeting the axis at  $b$ . Set off  $Ae, AF$ , each equal to  $Bb$ ; and draw  $KeL$  perpendicular to the axis. Then  $KL$  is the directrix and  $F$  is the focus. Through  $F$  and any number of points,  $o, o$ , etc., in the axis, draw double ordinates,  $no n$ , etc., and from the centre  $F$ , with the radii  $Fe, oe$ , etc., cut the respective ordinates at  $E, G, n, n$ , etc. The curve may be traced through these points as shown.

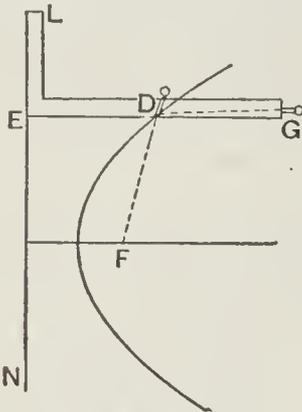

FIG. 56.

**2d Method:** By means of a square and a cord (Fig. 56).—Place a straight-edge to the directrix  $EN$ , and apply to it a square  $LEG$ . Fasten to the end  $G$  one end of a thread or cord equal in length to the edge  $EG$ , and attach the other end to the focus  $F$ ; slide the square along the straight-edge, holding the cord taut against the edge of the square by a pencil  $D$ , by which the curve is described.

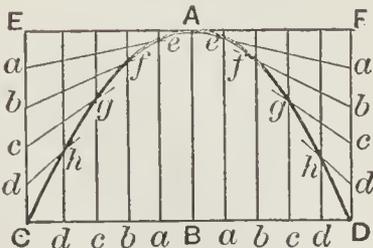

FIG. 57.

**3d Method:** When the height and the base are given (Fig. 57).—Let  $AB$  be the given axis, and  $CD$  a double ordinate or base; to describe a parabola of which the vertex is at  $A$ . Through  $A$  draw  $EF$  parallel to  $CD$ , and through  $C$  and  $D$  draw  $CE$  and  $DF$  parallel to the axis. Divide  $BC$  and  $BD$  into any number of equal parts, say five, at  $a, b, c, d$ , and divide  $CE$  and  $DF$  into the same number of parts. Through the points  $a, b, c, d$  in the base  $CD$  on each side of the axis draw perpendiculars, and through  $a, b, c, d$  in  $CE$  and  $DF$  draw lines to the vertex  $A$ , cutting the perpendiculars at  $e, f, g, h$ . These are points in the parabola, and the curve  $CAD$  may be traced as shown, passing through them.

**47. The Hyperbola** (Fig. 58).—A hyperbola is a plane curve, such that the difference of the distances from any point of it to two fixed points is equal to a given distance. The fixed points are called the foci.

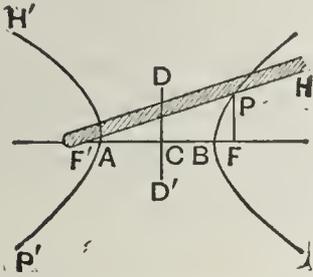

FIG. 58.

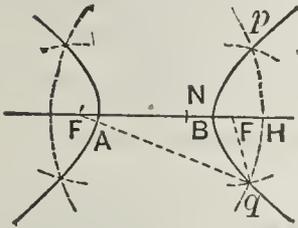

FIG. 59.

**To construct a hyperbola.**

—Let  $F'$  and  $F$  be the foci, and  $F'F$  the distance between them. Take a ruler longer than the distance  $F'F$ , and fasten one of its extremities at the focus  $F'$ . At the other extremity,  $H$ , attach a thread of such a length that the length of the ruler shall exceed the length of the thread by a given distance  $AB$ . Attach the other extremity of the thread at the focus  $F$ .

Press a pencil,  $P$ , against the ruler, and keep the thread constantly tense, while the ruler is turned around  $F'$  as a centre. The point of the pencil will describe one branch of the curve.

*2d Method:* By points (Fig. 59).—From the focus  $F'$  lay off a distance  $F'N$  equal to the transverse axis, or distance between the two branches of the curve, and take any other distance, as  $F'H$ , greater than  $F'N$ .

With  $F'$  as a centre and  $F'H$  as a radius describe the arc of a circle. Then with  $F$  as a centre and  $NH$  as a radius describe an arc intersecting the arc before described at  $p$  and  $q$ .

These will be points of the hyperbola, for  $F'q - F'p$  is equal to the transverse axis  $AB$ .

If, with  $F$  as a centre and  $F'H$  as a radius, an arc be described, and a second arc be described with  $F'$  as a centre and  $NH$  as a radius, two points in the other branch of the curve will be determined. Hence, by changing the centres, each pair of radii will determine two points in each branch.

**The Equilateral Hyperbola.**—The transverse axis of a hyperbola is the distance, on a line joining the foci, between the two branches of the curve. The conjugate axis is a line perpendicular to the transverse axis, drawn from its centre, and of such a length that the diagonal of the rectangle of the transverse and conjugate axes is equal to the distance between the foci. The diagonals of this rectangle, indefinitely prolonged, are the *asymptotes* of the hyperbola, lines which the curve continually approaches, but touches only at an infinite distance. If these asymptotes are perpendicular to each other, the hyperbola is called a *rectangular* or *equilateral hyperbola*. It is a property of this hyperbola that if the asymptotes are taken as axes of a rectangular system of coördinates (see Analytical Geometry), the product of the abscissa and ordinate of any point in the curve is equal to the product of the abscissa and ordinate of any other point; or, if  $p$  is the ordinate of any point and  $v$  its abscissa, and  $p_1$  and  $v_1$  are the ordinate and abscissa of any other point,  $pv = p_1 v_1$ ; or  $pv = a$  constant.

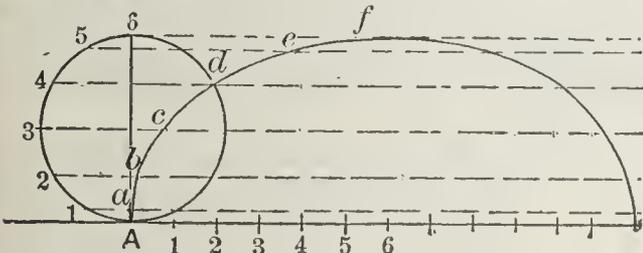

FIG. 60.

**48. The Cycloid**

(Fig. 60).—If a circle  $Aa$  be rolled along a straight line  $A6$ , any point of the circumference as  $A$  will describe a curve, which is called a cycloid. The circle is called the generating circle, and  $A$  the generating point.

**To draw a cycloid.**

—Divide the circumference of the generating circle into an even number of equal parts, as  $A 1, 2$ , etc., and set off these distances on the base. Through the points  $1, 2, 3$ , etc., on the circle draw horizontal lines, and on them set off distances  $1a = A1, 2b = A2, 3c = A3$ , etc. The points  $A, a, b, c$ , etc., will be points in the cycloid, through which draw the curve.

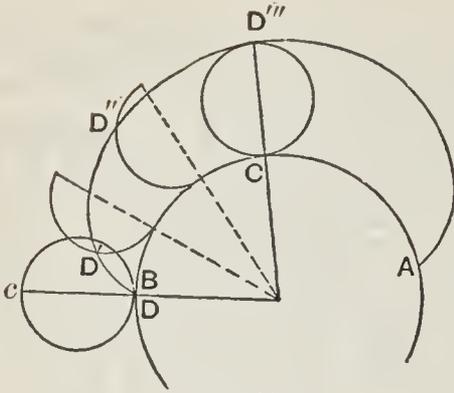

FIG. 61.

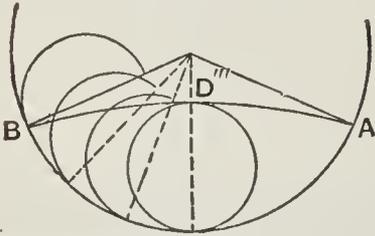

FIG. 62.

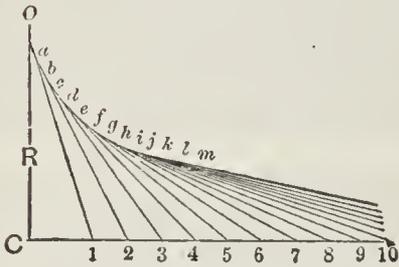

FIG. 63.

**52. The Spiral.**—The spiral is a curve described by a point which moves along a straight line according to any given law, the line at the same time having a uniform angular motion. The line is called the radius vector.

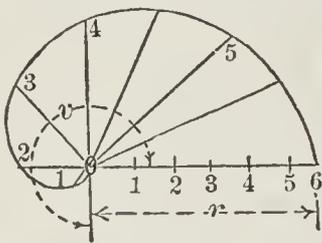

FIG. 64.

If the radius vector increases directly as the measuring angle, the spires, or parts described in each revolution, thus gradually increasing their distance from each other, the curve is known as the spiral of Archimedes (Fig. 64).

This curve is commonly used for cams. To describe it draw the radius vector in several different directions around the centre, with equal angles between them; set off the distances 1, 2, 3, 4, etc., corresponding to the scale upon which the curve is drawn, as shown in Fig. 64.

In the common spiral (Fig. 64) the pitch is uniform; that is, the spires are equidistant. Such a spiral is made by rolling up a belt of uniform thickness.

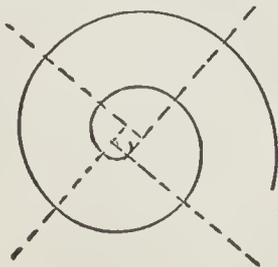

Fig. 65.

**49. The Epicycloid** (Fig. 61) is generated by a point  $D$  in one circle  $DC$  rolling upon the circumference of another circle  $ACB$ , instead of on a flat surface or line; the former being the generating circle, and the latter the fundamental circle. The generating circle is shown in four positions, in which the generating point is successively marked  $D, D', D'', D'''$ .  $AD''B$  is the epicycloid.

**50. The Hypocycloid** (Fig. 62) is generated by a point in the generating circle rolling on the inside of the fundamental circle.

When the generating circle = radius of the other circle, the hypocycloid becomes a straight line.

**51. The Tractrix or Schiele's anti-friction curve** (Fig. 63).— $R$  is the radius of the shaft,  $C, 1, 2$ , etc., the axis. From  $O$  set off on  $R$  a small distance,  $oa$ ; with radius  $R$  and centre  $a$  cut the axis at 1, join  $a1$ , and set off a like small distance  $ab$ ; from  $b$  with radius  $R$  cut axis at 2, join  $b2$ , and so on, thus finding points  $o, a, b, c, d$ , etc., through which the curve is to be drawn.

**To construct a spiral with four centres** (Fig. 65).—Given the pitch of the spiral, construct a square about the centre, with the sum of the four sides equal to the pitch. Prolong the sides in one direction as shown; the corners are the centres for each arc of the external angles, forming a quadrant of a spire.

**53. To find the diameter of a circle into which a certain number of rings will fit on its inside** (Fig. 66).—For instance, what is the diameter of a circle into which twelve  $\frac{1}{2}$ -inch rings will fit, as per sketch? Assume that we have found the diameter of the required

circle, and have drawn the rings inside of it. Join the centres of the rings by straight lines, as shown: we then obtain a regular polygon with 12 sides, each side being equal to the diameter of a given ring. We have now to find the diameter of a circle circumscribed about this polygon, and add the diameter of one ring to it; the sum will be the diameter of the circle into which the rings will fit. Through the centres *A* and *D* of two adjacent rings draw the radii *CA* and *CD*; since the polygon has twelve sides the angle  $\angle ACD = 30^\circ$  and  $\angle ACB = 15^\circ$ . One half of the side *AD* is equal to *AB*. We now give the following proportion: The sine of the angle  $\angle ACB$  is to *AB* as 1 is to the required radius. From this we get the following

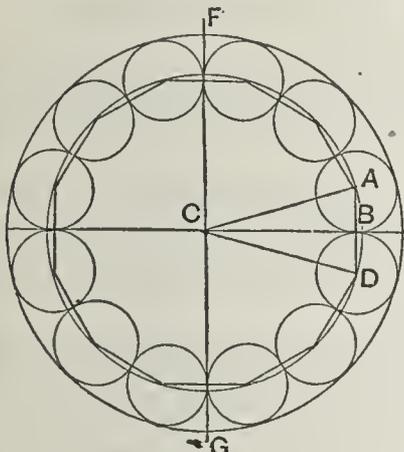

FIG. 66.

rule: Divide *AB* by the sine of the angle  $\angle ACB$ ; the quotient will be the radius of the circumscribed circle; add to the corresponding diameter the diameter of one ring; the sum will be the required diameter *FG*.

**54. To describe an arc of a circle which is too large to be drawn by a beam compass, by means of points in the arc, radius being given.**—Suppose the radius is 20 feet and it is desired to obtain five points in an arc whose half chord is 4 feet. Draw a line equal to the half chord, full size, or on a smaller scale if more convenient, and erect a perpendicular at one end, thus making rectangular axes of coördinates. Erect perpendiculars at points 1, 2, 3, and 4 feet from the first perpendicular. Find values of *y* in the formula of the circle,  $x^2 + y^2 = R^2$  by substituting for *x* the values 0, 1, 2, 3, and 4, etc., and for *R*<sup>2</sup> the square of the radius, or 400. The values will be  $y = \sqrt{R^2 - x^2} = \sqrt{400}, \sqrt{399}, \sqrt{396}, \sqrt{391}, \sqrt{384}; = 20, 19.975, 19.90, 19.774, 19.596$ .

Subtract the smallest, or 19.596, leaving 0.404, 0.379, 0.304, 0.178, 0 feet. Lay off these distances on the five perpendiculars, as ordinates from the half chord, and the positions of five points on the arc will be found.

Through these the curve may be drawn. (See also Problem 14.)

**55. The Catenary** is the curve assumed by a perfectly flexible cord when its ends are fastened at two points, the weight of a unit length being constant.

The equation of the catenary is  $y = \frac{a}{2} \left( e^{\frac{x}{a}} + e^{-\frac{x}{a}} \right)$ , in which *e* is the base of the Napierian system of logarithms.

**To plot the catenary.**—Let *o* (Fig. 67) be the origin of coördinates. Assigning to *a* any value as 3, the equation becomes

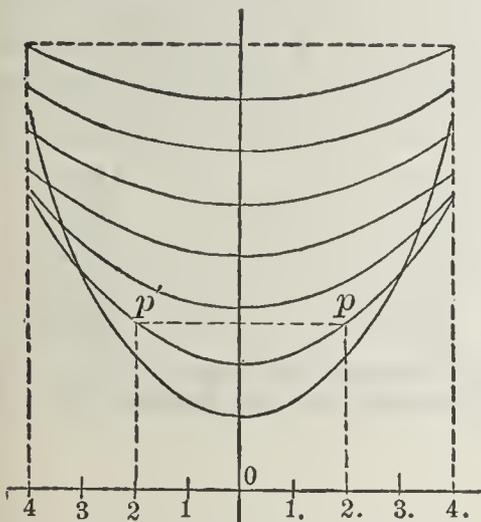

FIG. 67.

$$y = \frac{3}{2} \left( e^{\frac{x}{3}} + e^{-\frac{x}{3}} \right).$$

To find the lowest point of the curve.

Put  $x = 0$ ;  $\therefore y = \frac{3}{2} \left( e^0 + e^{-0} \right) = \frac{3}{2} (1 + 1) = 3$ .

Then put  $x = 1$ ;  $\therefore y = \frac{3}{2} \left( e^{\frac{1}{3}} + e^{-\frac{1}{3}} \right) = \frac{3}{2} (1.396 + 0.717) = 3.17$ .

Put  $x = 2$ ;  $\therefore y = \frac{3}{2} \left( e^{\frac{2}{3}} + e^{-\frac{2}{3}} \right) = \frac{3}{2} (1.948 + 0.513) = 3.69$ .

Put  $x = 3, 4, 5$ , etc., etc., and find the corresponding values of  $y$ . For each value of  $y$  we obtain two symmetrical points, as for example  $p$  and  $p^1$ . In this way, by making  $a$  successively equal to 2, 3, 4, 5, 6, 7, and 8, the curves of Fig. 67 were plotted.

In each case the distance from the origin to the lowest point of the curve is equal to  $a$ ; for putting  $x = 0$ , the general equation reduces to  $y = a$ .

For values of  $a = 6, 7$ , and 8 the catenary closely approaches the parabola. For derivation of the equation of the catenary see Bowser's Analytic Mechanics. For comparison of the catenary with the parabola, see article by F. R. Honey, *Amer. Machinist*, Feb. 1, 1894.

**56. The Involute** is a name given to the curve which is formed by the end of a string which is unwound from a cylinder and kept taut; consequently the string as it is unwound will always lie in the direction of a tangent to the cylinder. To describe the involute of any given circle, Fig. 68, take any point  $A$  on its circumference, draw a diameter  $AB$ , and from  $B$  draw  $Bb$  perpendicular to  $AB$ . Make  $Bb$  equal in length to half the circumference of the circle. Divide  $Bb$  and the semi-circumference into the same number of equal parts, say six. From each point of division 1, 2, 3, etc., on the circumference draw lines to the centre  $C$  of the circle. Then draw  $1a$  perpendicular to  $C1$ ;  $2a_2$  perpendicular to  $C2$ ; and so on. Make  $1a$  equal to  $bb_1$ ;  $2a_2$  equal to  $bb_2$ ;  $3a_3$  equal to  $bb_3$ ; and so on.

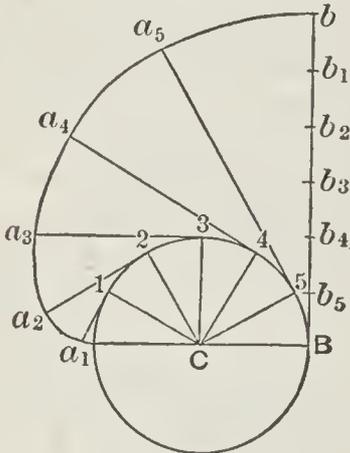

FIG. 68.

Join the points  $A, a_1, a_2, a_3$ , etc., by a curve; this curve will be the required involute.

**57. Method of plotting angles without using a protractor.**—The radius of a circle whose circumference is 360 is 57.3 (more accurately 57.296). Striking a semicircle with a radius 57.3 by any scale, spacers set to 10 by the same scale will divide the arc into 18 spaces of  $10^\circ$  each, and intermediates can be measured indirectly at the rate of 1 by scale for each  $1^\circ$ , or interpolated by eye according to the degree of accuracy required. The following table shows the chords to the above-mentioned radius, for every 10 degrees from  $0^\circ$  up to  $110^\circ$ . By means of one of these,

Angle.	Chord.	Angle.	Chord.
$1^\circ$ .....	0.999	$60^\circ$ .....	57.296
$10^\circ$ .....	9.988	$70^\circ$ .....	65.727
$20^\circ$ .....	19.899	$80^\circ$ .....	73.658
$30^\circ$ .....	29.658	$90^\circ$ .....	81.029
$40^\circ$ .....	39.192	$100^\circ$ .....	87.782
$50^\circ$ ..	48.429	$110^\circ$ .....	93.869

a  $10^\circ$  point is fixed upon the paper next less than the required angle, and the remainder is laid off at the rate of 1 by scale for each degree.

## GEOMETRICAL PROPOSITIONS.

In a right-angled triangle the square on the hypotenuse is equal to the sum of the squares on the other two sides.

If a triangle is equilateral, it is equiangular, and *vice versa*.

If a straight line from the vertex of an isosceles triangle bisects the base, it bisects the vertical angle and is perpendicular to the base.

If one side of a triangle is produced, the exterior angle is equal to the sum of the two interior and opposite angles.

If two triangles are mutually equiangular, they are similar and their corresponding sides are proportional.

If the sides of a polygon are produced in the same order, the sum of the exterior angles equals four right angles. (Not true if the polygon has re-entering angles)

In a quadrilateral, the sum of the interior angles equals four right angles.

In a parallelogram, the opposite sides are equal; the opposite angles are equal; it is bisected by its diagonal, and its diagonals bisect each other.

If three points are not in the same straight line, a circle may be passed through them.

If two arcs are intercepted on the same circle, they are proportional to the corresponding angles at the centre.

If two arcs are similar, they are proportional to their radii.

The areas of two circles are proportional to the squares of their radii.

If a radius is perpendicular to a chord, it bisects the chord and it bisects the arc subtended by the chord.

A straight line tangent to a circle meets it in only one point, and it is perpendicular to the radius drawn to that point.

If from a point without a circle tangents are drawn to touch the circle, there are but two; they are equal, and they make equal angles with the chord joining the tangent points.

If two lines are parallel chords or a tangent and parallel chord, they intercept equal arcs of a circle.

If an angle at the circumference of a circle, between two chords, is subtended by the same arc as an angle at the centre, between two radii, the angle at the circumference is equal to half the angle at the centre.

If a triangle is inscribed in a semicircle, it is right-angled.

If two chords intersect each other in a circle, the rectangle of the segments of the one equals the rectangle of the segments of the other.

And if one chord is a diameter and the other perpendicular to it, the rectangle of the segments of the diameter is equal to the square on half the other chord, and the half chord is a mean proportional between the segments of the diameter.

If an angle is formed by a tangent and chord, it is measured by one half of the arc intercepted by the chord; that is, it is equal to half the angle at the centre subtended by the chord.

*Degree of a Railway Curve.*—This last proposition is useful in staking out railway curves. A curve is designated as one of so many degrees, and the degree is the angle at the centre subtended by a chord of 100 ft. To lay out a curve of  $n$  degrees the transit is set at its beginning or "point of curve," pointed in the direction of the tangent, and turned through  $\frac{1}{2}n$  degrees; a point 100 ft. distant in the line of sight will be a point in the curve. The transit is then swung  $\frac{1}{2}n$  degrees further and a 100 ft. chord is measured from the point already found to a point in the new line of sight, which is a second point or "station" in the curve.

The radius of a  $1^\circ$  curve is 5729.65 ft., and the radius of a curve of any degree is 5729.65 ft. divided by the number of degrees.

## MENSURATION.

## PLANE SURFACES.

**Quadrilateral.**—A four-sided figure.

**Parallelogram.**—A quadrilateral with opposite sides parallel.

*Varieties.*—Square: four sides equal, all angles right angles. Rectangle: opposite sides equal, all angles right angles. Rhombus: four sides equal, opposite angles equal, angles not right angles. Rhomboid: opposite sides equal, opposite angles equal, angles not right angles.

**Trapezium.**—A quadrilateral with unequal sides.

**Trapezoid.**—A quadrilateral with only one pair of opposite sides parallel.

**Diagonal of a square** =  $\sqrt{2 \times \text{side}^2} = 1.4142 \times \text{side}$ .

**Diag. of a rectangle** =  $\sqrt{\text{sum of squares of two adjacent sides}}$ .

**Area of any parallelogram** = base  $\times$  altitude.

**Area of rhombus or rhomboid** = product of two adjacent sides  $\times$  sine of angle included between them.

**Area of a trapezium** = half the product of the diagonal by the sum of the perpendiculars let fall on it from opposite angles.

**Area of a trapezoid** = product of half the sum of the two parallel sides by the perpendicular distance between them.

**To find the area of any quadrilateral figure.**—Divide the quadrilateral into two triangles; the sum of the areas of the triangles is the area.

Or, multiply half the product of the two diagonals by the sine of the angle at their intersection.

**To find the area of a quadrilateral inscribed in a circle.**—From half the sum of the four sides subtract each side severally; multiply the four remainders together; the square root of the product is the area.

**Triangle.**—A three-sided plane figure.

*Varieties.*—Right-angled, having one right angle; obtuse-angled, having one obtuse angle; isosceles, having two equal angles and two equal sides; equilateral, having three equal sides and equal angles.

The sum of the three angles of every triangle =  $180^\circ$ .

The sum of the two acute angles of a right-angled triangle =  $90^\circ$ .

**Hypotenuse of a right-angled triangle, the side opposite the right angle,** =  $\sqrt{\text{sum of the squares of the other two sides}}$ . If  $a$  and  $b$  are the two sides and  $c$  the hypotenuse,  $c^2 = a^2 + b^2$ ;  $a = \sqrt{c^2 - b^2} = \sqrt{(c+b)(c-b)}$ .

**To find the area of a triangle:**

**RULE 1.** Multiply the base by half the altitude.

**RULE 2.** Multiply half the product of two sides by the sine of the included angle.

**RULE 3.** From half the sum of the three sides subtract each side severally; multiply together the half sum and the three remainders, and extract the square root of the product.

The area of an equilateral triangle is equal to one fourth the square of one of its sides multiplied by the square root of 3, =  $\frac{a^2 \sqrt{3}}{4}$ ,  $a$  being the side; or  $a^2 \times .433013$ .

**Hypotenuse and one side of right-angled triangle given, to find other side,** Required side =  $\sqrt{\text{hyp}^2 - \text{given side}^2}$ .

If the two sides are equal, side = hyp  $\div$  1.4142; or hyp  $\times$  .7071.

**Area of a triangle given, to find base:** Base = twice area  $\div$  perpendicular height

**Area of a triangle given, to find height:** Height = twice area  $\div$  base.

**Two sides and base given, to find perpendicular height (in a triangle in which both of the angles at the base are acute).**

**RULE.**—As the base is to the sum of the sides, so is the difference of the sides to the difference of the divisions of the base made by drawing the perpendicular. Half this difference being added to or subtracted from half the base will give the two divisions thereof. As each side and its opposite

(Division of the base constitutes a right-angled triangle, the perpendicular is ascertained by the rule perpendicular =  $\sqrt{\text{hyp}^2 - \text{base}^2}$ .

**Polygon.**—A plane figure having three or more sides. Regular or irregular, according as the sides or angles are equal or unequal. Polygons are named from the number of their sides and angles.

**To find the area of an irregular polygon.**—Draw diagonals dividing the polygon into triangles, and find the sum of the areas of these triangles.

**To find the area of a regular polygon :**

**RULE.**—Multiply the length of a side by the perpendicular distance to the centre; multiply the product by the number of sides, and divide it by 2. Or, multiply half the perimeter by the perpendicular let fall from the centre on one of the sides.

The perpendicular from the centre is equal to half of one of the sides of the polygon multiplied by the cotangent of the angle subtended by the half side.

The angle at the centre =  $360^\circ$  divided by the number of sides.

TABLE OF REGULAR POLYGONS.

No. of Sides.	Name of Polygon.	Area, Side = 1.	Radius of Circumscribed Circle.		Radius of Inscribed Circle, Side = 1.	Length of Side, Radius of Circumscribed Circle = 1.	Angle at Centre.	Angle between Adjacent Sides.
			Perpen. from Centre = 1.	Side = 1.

**To find the area of a regular polygon, when the length of a side only is given :**

**RULE.**—Multiply the square of the side by the multiplier opposite to the name of the polygon in the table.

**To find the area of an irregular figure** (Fig. 69).—Draw ordinates across its breadth at equal distances apart, the first and the last ordinate each being one half space from the ends of the figure. Find the average breadth by adding together the lengths of these lines included between the boundaries of the figure, and divide by the number of the lines added; multiply this mean breadth by the length. The greater the number of lines the nearer the approximation.

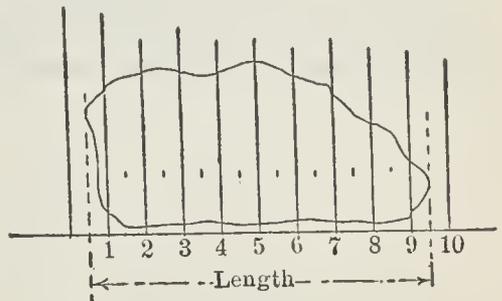

FIG. 69.

In a figure of very irregular outline, as an indicator-diagram from a high-speed steam-engine, mean lines may be substituted for the actual lines of the figure, being so traced as to intersect the undulations, so that the total area of the spaces cut off may be compensated by that of the extra spaces inclosed.

**2d Method: THE TRAPEZOIDAL RULE.**—Divide the figure into any sufficient number of equal parts; add half the sum of the two end ordinates to the sum of all the other ordinates; divide by the number of spaces (that is, one less than the number of ordinates) to obtain the mean ordinate, and multiply this by the length to obtain the area.

**3d Method: SIMPSON'S RULE.**—Divide the length of the figure into any even number of equal parts, at the common distance  $D$  apart, and draw ordinates through the points of division to touch the boundary lines. Add together the first and last ordinates and call the sum  $A$ ; add together the even ordinates and call the sum  $B$ ; add together the odd ordinates, except the first and last, and call the sum  $C$ . Then,

$$\text{area of the figure} = \frac{A + 4B + 2C}{3} \times D.$$

**4th Method: DURAND'S RULE.**—Add together  $4/10$  the sum of the first and last ordinates,  $1\ 1/10$  the sum of the second and the next to the last (or the penultimates), and the sum of all the intermediate ordinates. Multiply the sum thus gained by the common distance between the ordinates to obtain the area, or divide this sum by the number of spaces to obtain the mean ordinate.

Prof. Durand describes the method of obtaining his rule in *Engineering News*, Jan. 18, 1894. He claims that it is more accurate than Simpson's rule, and practically as simple as the trapezoidal rule. He thus describes its application for approximate integration of differential equations. Any definite integral may be represented graphically by an area. Thus, let

$$Q = \int u \, dx$$

be an integral in which  $u$  is some function of  $x$ , either known or admitting of computation or measurement. Any curve plotted with  $x$  as abscissa and  $u$  as ordinate will then represent the variation of  $u$  with  $x$ , and the area between such curve and the axis  $X$  will represent the integral in question, no matter how simple or complex may be the real nature of the function  $u$ .

Substituting in the rule as above given the word "volume" for "area" and the word "section" for "ordinate," it becomes applicable to the determination of volumes from equidistant sections as well as of areas from equidistant ordinates.

Having approximately obtained an area by the trapezoidal rule, the area by Durand's rule may be found by adding algebraically to the sum of the ordinates used in the trapezoidal rule (that is, half the sum of the end ordinates + sum of the other ordinates)  $1/10$  of (sum of penultimates — sum of first and last) and multiplying by the common distance between the ordinates.

**5th Method**—Draw the figure on cross-section paper. Count the number of squares that are entirely included within the boundary; then estimate the fractional parts of squares that are cut by the boundary, add together these fractions, and add the sum to the number of whole squares. The result is the area in units of the dimensions of the squares. The finer the ruling of the cross-section paper the more accurate the result.

**6th Method.**—Use a planimeter.

**7th Method.**—With a chemical balance, sensitive to one milligram, draw the figure on paper of uniform thickness and cut it out carefully; weigh the piece cut out, and compare its weight with the weight per square inch of the paper as tested by weighing a piece of rectangular shape.

**THE CIRCLE.**

Circumference = diameter × 3.1416, nearly; more accurately, 3.14159265359.  
 Approximations,  $\frac{22}{7} = 3.143$ ;  $\frac{355}{113} = 3.1415929$ .

The ratio of circum. to diam. is represented by the symbol  $\pi$  (called *Pi*).

Multiples of $\pi$ .	Multiples of $\frac{\pi}{4}$ .
$1\pi = 3.14159265359$	$\frac{1}{4}\pi = .7853982$
$2\pi = 6.28318530718$	“ × 2 = 1.5707963
$3\pi = 9.42477796077$	“ × 3 = 2.3561945
$4\pi = 12.56637061436$	“ × 4 = 3.1415927
$5\pi = 15.70796326795$	“ × 5 = 3.9269908
$6\pi = 18.84955592154$	“ × 6 = 4.7123890
$7\pi = 21.99114857513$	“ × 7 = 5.4977871
$8\pi = 25.13274122872$	“ × 8 = 6.2831853
$9\pi = 28.27433388231$	“ × 9 = 7.0685835

Ratio of diam. to circumference = reciprocal of  $\pi = 0.3183099$ .

Reciprocal of $\frac{1}{4}\pi = 1.27324$ .	$\frac{7}{\pi} = 2.22817$	$\frac{1}{12}\pi = 0.261799$
Multiples of $\frac{1}{\pi}$ .	$\frac{8}{\pi} = 2.54648$	$\frac{\pi}{360} = 0.0087266$
$\frac{1}{\pi} = .31831$	$\frac{9}{\pi} = 2.86479$	$\frac{360}{\pi} = 114.5915$
$\frac{2}{\pi} = .63662$	$\frac{10}{\pi} = 3.18310$	$\pi^2 = 9.86960$
$\frac{3}{\pi} = .95493$	$\frac{12}{\pi} = 3.81972$	$\frac{1}{\pi^2} = 0.101321$
$\frac{4}{\pi} = 1.27324$	$\frac{1}{2}\pi = 1.570796$	$\sqrt{\pi} = 1.772453$
$\frac{5}{\pi} = 1.59155$	$\frac{1}{3}\pi = 1.047197$	$\sqrt{\frac{1}{\pi}} = 0.564189$
$\frac{6}{\pi} = 1.90986$	$\frac{1}{6}\pi = 0.523599$	Log $\pi = 0.49714987$
		Log $\frac{1}{4}\pi = \bar{1}.895090$

Diam. in ins. =  $13.5405 \sqrt{\text{area in sq. ft.}}$

Area in sq. ft. = (diam. in inches)<sup>2</sup> × .0054542.

$D$  = diameter,  $R$  = radius,  $C$  = circumference,  $A$  = area.

$$C = \pi D; = 2\pi R; = \frac{4A}{D}; = 2\sqrt{\pi A}; = 3.545\sqrt{A};$$

$$A = D^2 \times .7854; = \frac{CR}{2}; = 4R^2 \times .7854; = \pi R^2; = \frac{1}{4}\pi D^2; = \frac{C^2}{4\pi}; = .07958C^2; = \frac{CD}{4}.$$

$$D = \frac{C}{\pi}; = 0.31831C; \{ = 2\sqrt{\frac{A}{\pi}}; = 1.12838\sqrt{A};$$

$$R = \frac{C}{2\pi}; = 0.159155C; = \sqrt{\frac{A}{\pi}}; = 0.564189\sqrt{A}.$$

Areas of circles are to each other as the squares of their diameters.

**To find the length of an arc of a circle:**

RULE 1. As 360 is to the number of degrees in the arc, so is the circumference of the circle to the length of the arc.

RULE 2. Multiply the diameter of the circle by the number of degrees in the arc, and this product by 0.0087266.

### Relations of Arc, Chord, Chord of Half the Arc, Versed Sine, etc.

Let  $R$  = radius,  $D$  = diameter,  $Arc$  = length of arc,  
 $Cd$  = chord of the arc,  $ch$  = chord of half the arc,  
 $V$  = versed sine, or height of the arc,

$$Arc = \frac{8ch - Cd}{3} \text{ (very nearly), } = \frac{\sqrt{Cd^2 + 4V^2} \times 10V^2}{15Cd^2 + 33V^2} + 2ch, \text{ nearly.}$$

$$Arc = \frac{2ch \times 10V}{60D - 27V} + 2ch, \text{ nearly.}$$

$$\begin{aligned} \text{Chord of the arc} &= 2\sqrt{ch^2 - V^2}; = \sqrt{D^2 - (D - 2V)^2}; = 8ch - 3Arc. \\ &= 2\sqrt{R^2 - (R - V)^2}; = 2\sqrt{(D - V) \times V}. \end{aligned}$$

$$\text{Chord of half the arc, } ch = \frac{1}{2}\sqrt{Cd^2 + 4V^2}; = \sqrt{D \times V}; = \frac{3Arc + Cd}{8}.$$

$$\text{Diameter} = \frac{ch^2}{V}; = \frac{\left(\frac{1}{2}Cd\right)^2 + V^2}{V};$$

$$\text{Versed sine} = \frac{ch^2}{D}; = \frac{1}{2}(D - \sqrt{D^2 - Cd^2})$$

$$\text{(or } \frac{1}{2}(D + \sqrt{D^2 - Cd^2}), \text{ if } V \text{ is greater than radius}$$

$$= \sqrt{ch^2 - \frac{Cd^2}{4}}.$$

Half the chord of the arc is a mean proportional between the versed sine and diameter minus versed sine:  $\frac{1}{2}Cd = \sqrt{V \times (D - V)}$

**Length of the Chord** subtending an angle at the centre = twice the sine of half the angle. (See Table of Sines, p. 157.)

#### Length of a Circular Arc.—Huyghens's Approximation.

Let  $C$  represent the length of the chord of the arc and  $c$  the length of the chord of half the arc; the length of the arc

$$L = \frac{8c - C}{3}.$$

Professor Williamson shows that when the arc subtends an angle of  $30^\circ$ , the radius being 100,000 feet (nearly 19 miles), the error by this formula is about two inches, or  $\frac{1}{600000}$  part of the radius. When the length of the arc is equal to the radius, i.e., when it subtends an angle of  $57^\circ.3$ , the error is less than  $\frac{1}{7680}$  part of the radius. Therefore, if the radius is 100,000 feet, the error is less than  $\frac{100000}{7680} = 13$  feet. The error increases rapidly with the increase of the angle subtended.

In the measurement of an arc which is described with a short radius the error is so small that it may be neglected. Describing an arc with a radius of 12 inches subtending an angle of  $30^\circ$ , the error is  $\frac{1}{50000}$  of an inch. For  $57^\circ.3$  the error is less than  $0''.0015$ .

In order to measure an arc when it subtends a large angle, bisect it and measure each half as before—in this case making  $B$  = length of the chord of half the arc, and  $b$  = length of the chord of one fourth the arc; then

$$L = \frac{16b - 2B}{3}.$$

#### Relation of the Circle to its Equal, Inscribed, and Circumscribed Squares.

Diameter of circle	$\times .88623$	} = side of equal square.
Circumference of circle	$\times .28209$	
Circumference of circle	$\times 1.1284$	

Diameter of circle × .7071	} = side of inscribed square.
Circumference of circle × .22508	
Area of circle × .90031 ÷ diameter	
Area of circle × 1.2732	= area of circumscribed square.
Area of circle × .63662	= area of inscribed square.
Side of square × 1.4142	= diam. of circumscribed circle.
“ “ × 4.4428	= circum. “ “ “
“ “ × 1.1284	= diam. of equal circle.
“ “ × 3.5449	= circum. “ “ “
Perimeter of square × 0.88623	= “ “ “
Square inches × 1.2732	= circular inches.

**Sectors and Segments.**—To find the area of a sector of a circle.

RULE 1. Multiply the arc of the sector by half its radius.

RULE 2. As 360 is to the number of degrees in the arc, so is the area of the circle to the area of the sector.

RULE 3. Multiply the number of degrees in the arc by the square of the radius and by .008727.

To find the area of a segment of a circle: Find the area of the sector which has the same arc, and also the area of the triangle formed by the chord of the segment and the radii of the sector.

Then take the sum of these areas, if the segment is greater than a semi-circle, but take their difference if it is less.

Another Method: Area of segment =  $\frac{1}{2}R(\text{arc} - \sin A)$ , in which  $A$  is the central angle,  $R$  the radius, and arc the length of arc to radius 1

To find the area of a segment of a circle when its chord and height only are given. First find radius, as follows:

$$\text{radius} = \frac{1}{2} \left[ \frac{\text{square of half the chord}}{\text{height}} + \text{height} \right].$$

2. Find the angle subtended by the arc, as follows: half chord ÷ radius = sine of half the angle. Take the corresponding angle from a table of sines, and double it to get the angle of the arc.

3. Find area of the sector of which the segment is a part;  
area of sector = area of circle × degrees of arc ÷ 360.

4. Subtract area of triangle under the segment];  
Area of triangle = half chord × (radius - height of segment).

The remainder is the area of the segment.

When the chord, arc, and diameter are given, to find the area. From the length of the arc subtract the length of the chord. Multiply the remainder by the radius or one-half diameter; to the product add the chord multiplied by the height, and divide the sum by 2.

Given diameter,  $d$ , and height of segment,  $h$ .

$$\begin{aligned} \text{When } h \text{ is from } 0 \text{ to } \frac{1}{4}d, \text{ area} &= h \sqrt{1.766dh - h^2}; \\ \text{“ “ “ “ } \frac{1}{4}d \text{ to } \frac{1}{2}d, \text{ area} &= h \sqrt{0.017d^2 + 1.7dh - h^2} \end{aligned}$$

(approx.). Greatest error 0.23%, when  $h = \frac{1}{4}d$ .

To find the chord: From the diameter subtract the height; multiply the remainder by four times the height and extract the square root.

When the chords of the arc and of half the arc and the rise are given: To the chord of the arc add four thirds of the chord of half the arc; multiply the sum by the rise and the product by .40426 (approximate).

**Circular Ring.**—To find the area of a ring included between the circumferences of two concentric circles: Take the difference between the areas of the two circles; or, subtract the square of the less radius from the square of the greater, and multiply their difference by 3.14159.

The area of the greater circle is equal to  $\pi R^2$ ;  
and the area of the smaller,  $\pi r^2$ .

Their difference, or the area of the ring, is  $\pi(R^2 - r^2)$ .

**The Ellipse.**—Area of an ellipse = product of its semi-axes × 3.14159  
= product of its axes × .785398.

The Ellipse.—Circumference (approximate) =  $3.1416 \sqrt{\frac{D^2 + d^2}{2}}$ ,  $D$  and  $d$

being the two axes.

Trautwine gives the following as more accurate: When the longer axis  $D$  is not more than five times the length of the shorter axis,  $d$ ,

$$\text{Circumference} = 3.1416 \sqrt{\frac{D^2 + d^2}{2} - \frac{(D-d)^2}{8.8}}$$

When  $D$  is more than  $5d$ , the divisor 8.8 is to be replaced by the following:  
 For  $D/d = 6$  7 8 9 10 12 14 16 18 20 30 40 50  
 Divisor = 9 9.2 9.3 9.35 9.4 9.5 9.6 9.68 9.75 9.8 9.92 9.98 10

An accurate formula is  $C = \pi(a + b) \left( 1 + \frac{A^2}{4} + \frac{A^4}{16} + \frac{A^6}{256} + \frac{25A^8}{16384} + \dots \right)$ , in which  $A = \frac{a-b}{a+b}$ .—*Ingenieurs Taschenbuch*, 1896.

Carl G. Barth (*Machinery*, Sept., 1900) gives as a very close approximation to this formula

$$C = \pi(a + b) \frac{64 - 3A^4}{64 - 16A^2}$$

**Area of a segment of an ellipse** the base of which is parallel to one of the axes of the ellipse. Divide the height of the segment by the axis of which it is part, and find the area of a circular segment, in a table of circular segments, of which the height is equal to the quotient; multiply the area thus found by the product of the two axes of the ellipse.

**Cycloid.**—A curve generated by the rolling of a circle on a plane.

Length of a cycloidal curve =  $4 \times$  diameter of the generating circle.

Length of the base = circumference of the generating circle.

Area of a cycloid =  $3 \times$  area of generating circle.

**Helix (Screw).**—A line generated by the progressive rotation of a point around an axis and equidistant from its centre.

**Length of a helix.**—To the square of the circumference described by the generating-point add the square of the distance advanced in one revolution, and take the square root of their sum multiplied by the number of revolutions of the generating point. Or,

$$\sqrt{(c^2 + h^2)n} = \text{length, } n \text{ being number of revolutions.}$$

**Spirals.**—Lines generated by the progressive rotation of a point around a fixed axis, with a constantly increasing distance from the axis.

A *plane spiral* is when the point rotates in one plane.

A *conical spiral* is when the point rotates around an axis at a progressing distance from its centre, and advancing in the direction of the axis, as around a cone.

**Length of a plane spiral line.**—When the distance between the coils is uniform.

**RULE.**—Add together the greater and less diameters; divide their sum by 2; multiply the quotient by 3.1416, and again by the number of revolutions. Or, take the mean of the length of the greater and less circumferences and multiply it by the number of revolutions. Or,

$$\text{length} = \pi n \frac{d + d'}{2}, \text{ } d \text{ and } d' \text{ being the inner and outer diameters.}$$

**Length of a conical spiral line.**—Add together the greater and less diameters; divide their sum by 2 and multiply the quotient by 3.1416. To the square of the product of this circumference and the number of revolutions of the spiral add the square of the height of its axis and take the square root of the sum.

$$\text{Or, length} = \sqrt{\left(\pi n \frac{d + d'}{2}\right)^2 + h^2}$$

## SOLID BODIES.

**The Prism.**—To find the surface of a right prism: Multiply the perimeter of the base by the altitude for the convex surface. To this add the areas of the two ends when the entire surface is required.

Volume of a prism = area of its base  $\times$  its altitude.

**The pyramid.**—Convex surface of a regular pyramid = perimeter of its base  $\times$  half the slant height. To this add area of the base if the whole surface is required.

Volume of a pyramid = area of base  $\times$  one third of the altitude.

*To find the surface of a frustum of a regular pyramid:* Multiply half the slant height by the sum of the perimeters of the two bases for the convex surface. To this add the areas of the two bases when the entire surface is required.

*To find the volume of a frustum of a pyramid:* Add together the areas of the two bases and a mean proportional between them, and multiply the sum by one third of the altitude. (Mean proportional between two numbers = square root of their product.)

**Wedge.**—A wedge is a solid bounded by five planes, viz.: a rectangular base, two trapezoids, or two rectangles, meeting in an edge, and two triangular ends. The altitude is the perpendicular drawn from any point in the edge to the plane of the base.

*To find the volume of a wedge:* Add the length of the edge to twice the length of the base, and multiply the sum by one sixth of the product of the height of the wedge and the breadth of the base.

**Rectangular prismoid.**—A rectangular prismoid is a solid bounded by six planes, of which the two bases are rectangles, having their corresponding sides parallel, and the four upright sides of the solids are trapezoids.

*To find the volume of a rectangular prismoid:* Add together the areas of the two bases and four times the area of a parallel section equally distant from the bases, and multiply the sum by one sixth of the altitude.

**Cylinder.**—Convex surface of a cylinder = perimeter of base  $\times$  altitude. To this add the areas of the two ends when the entire surface is required.

Volume of a cylinder = area of base  $\times$  altitude.

**Cone.**—Convex surface of a cone = circumference of base  $\times$  half the slant side. To this add the area of the base when the entire surface is required.

Volume of a cone = area of base  $\times$  one third of the altitude.

*To find the surface of a frustum of a cone:* Multiply half the side by the sum of the circumferences of the two bases for the convex surface; to this add the areas of the two bases when the entire surface is required.

*To find the volume of a frustum of a cone:* Add together the areas of the two bases and a mean proportional between them, and multiply the sum by one third of the altitude. Or, Vol. =  $0.2618a(b^2 + c^2 + bc)$ ;  $a$  = altitude;  $b$  and  $c$ , diams. of the two bases.

**Sphere.**—*To find the surface of a sphere:* Multiply the diameter by the circumference of a great circle; or, multiply the square of the diameter by 3.14159.

Surface of sphere =  $4 \times$  area of its great circle.

“ “ “ = convex surface of its circumscribing cylinder.

Surfaces of spheres are to each other as the squares of their diameters.

*To find the volume of a sphere:* Multiply the surface by one third of the radius; or, multiply the cube of the diameter by  $\pi/6$ ; that is, by 0.5236.

Value of  $\pi/6$  to 10 decimal places = .5235987756.

The volume of a sphere =  $2/3$  the volume of its circumscribing cylinder.

Volumes of spheres are to each other as the cubes of their diameters.

**Spherical triangle.**—*To find the area of a spherical triangle:* Compute the surface of the quadrantal triangle, or one eighth of the surface of the sphere. From the sum of the three angles subtract two right angles; divide the remainder by 90, and multiply the quotient by the area of the quadrantal triangle.

**Spherical polygon.**—*To find the area of a spherical polygon:* Compute the surface of the quadrantal triangle. From the sum of all the angles subtract the product of two right angles by the number of sides less two; divide the remainder by 90 and multiply the quotient by the area of the quadrantal triangle.

**The prismoid.**—The prismoid is a solid having parallel end areas, and may be composed of any combination of prisms, cylinders, wedges, pyramids, or cones or frustums of the same, whose bases and apices lie in the end areas.

Inasmuch as cylinders and cones are but special forms of prisms and pyramids, and warped surface solids may be divided into elementary forms of them, and since frustums may also be subdivided into the elementary forms, it is sufficient to say that all prismoids may be decomposed into prisms, wedges, and pyramids. If a formula can be found which is equally applicable to all of these forms, then it will apply to any combination of them. Such a formula is called

### The Prismoidal Formula.

Let  $A$  = area of the base of a prism, wedge, or pyramid;  
 $A_1, A_2, A_m$  = the two end and the middle areas of a prismoid, or of any of  
 its elementary solids;

$h$  = altitude of the prismoid or elementary solid;

$V$  = its volume;

$$V = \frac{h}{6}(A_1 + 4A_m + A_2).$$

For a prism,  $A_1, A_m$  and  $A_2$  are equal, =  $A$ ;  $V = \frac{h}{6} \times 6A = hA$ .

For a wedge with parallel ends,  $A_2 = 0, A_m = \frac{1}{2}A_1$ ;  $V = \frac{h}{6}(A_1 + 2A_1) = \frac{hA_1}{2}$ .

For a cone or pyramid,  $A_2 = 0, A_m = \frac{1}{4}A_1$ ;  $V = \frac{h}{6}(A_1 + A_1) = \frac{hA_1}{3}$ .

The prismoidal formula is a rigid formula for all prismoids. The only approximation involved in its use is in the assumption that the given solid may be generated by a right line moving over the boundaries of the end areas.

The area of the middle section is never the mean of the two end areas if the prismoid contains any pyramids or cones among its elementary forms. When the three sections are similar in form the *dimensions* of the middle area are always the means of the corresponding end dimensions. This fact often enables the dimensions, and hence the area of the middle section, to be computed from the end areas.

**Polyedrons.**—A polyedron is a solid bounded by plane polygons. A regular polyedron is one whose sides are all equal regular polygons.

*To find the surface of a regular polyedron.*—Multiply the area of one of the faces by the number of faces; or, multiply the square of one of the edges by the surface of a similar solid whose edge is unity.

A TABLE OF THE REGULAR POLYEDRONS WHOSE EDGES ARE UNITY.

Names.	No. of Faces.	Surface.	Volume.
Tetraedron.....	4	1.7320508	0.1178513
Hexaedron.....	6	6.0000000	1.0000000
Octaedron.....	8	3.4641016	0.4714045
Dodecaedron.....	12	20.6457288	7.6631189
Icosaedron.....	20	8.6602540	2.1816950

**To find the volume of a regular polyedron.**—Multiply the surface by one third of the perpendicular let fall from the centre on one of the faces; or, multiply the cube of one of the edges by the solidity of a similar polyedron whose edge is unity.

**Solid of revolution.**—The volume of any solid of revolution is equal to the product of the area of its generating surface by the length of the path of the centre of gravity of that surface.

The convex surface of any solid of revolution is equal to the product of the perimeter of its generating surface by the length of path of its centre of gravity.

**Cylindrical ring.**—Let  $d$  = outer diameter;  $d'$  = inner diameter;  
 $\frac{1}{2}(d - d')$  = thickness =  $t$ ;  $\frac{1}{4}\pi t^2$  = sectional area;  $\frac{1}{2}(d + d')$  = mean diameter =  $M$ ;  $\pi t$  = circumference of section;  $\pi M$  = mean circumference of ring; surface =  $\pi t \times \pi M$ ; =  $\frac{1}{4}\pi^2(d^2 - d'^2)$ ; =  $9.86965 t M$ ; =  $2.46741(d^2 - d'^2)$ ;

$$\text{volume} = \frac{1}{4}\pi t^2 M \pi; = 2.46741 t^2 M.$$

**Spherical zone.**—Surface of a spherical zone or segment of a sphere = its altitude  $\times$  the circumference of a great circle of the sphere. A great circle is one whose plane passes through the centre of the sphere.

*Volume of a zone of a sphere.*—To the sum of the squares of the radii of the ends add one third of the square of the height; multiply the sum by the height and by 1.5708.

**Spherical segment.**—Volume of a spherical segment with one base.—

Multiply half the height of the segment by the area of the base, and the cube of the height by .5236 and add the two products. Or, from three times the diameter of the sphere subtract twice the height of the segment; multiply the difference by the square of the height and by .5236. Or, to three times the square of the radius of the base of the segment add the square of its height, and multiply the sum by the height and by .5236.

**Spheroid or ellipsoid.**—When the revolution of the spheroid is about the transverse diameter it is *prolate*, and when about the conjugate it is *oblate*.

*Convex surface of a segment of a spheroid.*—Square the diameters of the spheroid, and take the square root of half their sum; then, as the diameter from which the segment is cut is to this root so is the height of the segment to the proportionate height of the segment to the mean diameter. Multiply the product of the other diameter and 3.1416 by the proportionate height.

*Convex surface of a frustum or zone of a spheroid.*—Proceed as by previous rule for the surface of a segment, and obtain the proportionate height of the frustum. Multiply the product of the diameter parallel to the base of the frustum and 3.1416 by the proportionate height of the frustum.

*Volume of a spheroid* is equal to the product of the square of the revolving axis by the fixed axis and by .5236. The volume of a spheroid is two thirds of that of the circumscribing cylinder.

*Volume of a segment of a spheroid.*—1. When the base is parallel to the revolving axis, multiply the difference between three times the fixed axis and twice the height of the segment, by the square of the height and by .5236. Multiply the product by the square of the revolving axis, and divide by the square of the fixed axis.

2. When the base is perpendicular to the revolving axis, multiply the difference between three times the revolving axis and twice the height of the segment by the square of the height and by .5236. Multiply the product by the length of the fixed axis, and divide by the length of the revolving axis.

*Volume of the middle frustum of a spheroid.*—1. When the ends are circular, or parallel to the revolving axis: To twice the square of the middle diameter add the square of the diameter of one end; multiply the sum by the length of the frustum and by .2618.

2. When the ends are elliptical, or perpendicular to the revolving axis: To twice the product of the transverse and conjugate diameters of the middle section add the product of the transverse and conjugate diameters of one end; multiply the sum by the length of the frustum and by .2618.

**Spindles.**—Figures generated by the revolution of a plane area, when the curve is revolved about a chord perpendicular to its axis, or about its double ordinate. They are designated by the name of the arc or curve from which they are generated, as Circular, Elliptic, Parabolic, etc., etc.

*Convex surface of a circular spindle, zone, or segment of it*—Rule: Multiply the length by the radius of the revolving arc; multiply this arc by the central distance, or distance between the centre of the spindle and centre of the revolving arc; subtract this product from the former, double the remainder, and multiply it by 3.1416

*Volume of a circular spindle.*—Multiply the central distance by half the area of the revolving segment; subtract the product from one third of the cube of half the length, and multiply the remainder by 12.5664.

*Volume of frustum or zone of a circular spindle.*—From the square of half the length of the whole spindle take one third of the square of half the length of the frustum, and multiply the remainder by the said half length of the frustum; multiply the central distance by the revolving area which generates the frustum; subtract this product from the former, and multiply the remainder by 6.2832.

*Volume of a segment of a circular spindle.*—Subtract the length of the segment from the half length of the spindle; double the remainder and ascertain the volume of a middle frustum of this length; subtract the result from the volume of the whole spindle and halve the remainder.

*Volume of a cycloidal spindle* = five eighths of the volume of the circumscribing cylinder.—Multiply the product of the square of twice the diameter of the generating circle and 3.927 by its circumference, and divide this product by 8.

**Parabolic conoid.**—*Volume of a parabolic conoid* (generated by the revolution of a parabola on its axis).—Multiply the area of the base by half the height.

Or multiply the square of the diameter of the base by the height and by .3927.

*Volume of a frustum of a parabolic conoid.*—Multiply half the sum of the areas of the two ends by the height.

*Volume of a parabolic spindle* (generated by the revolution of a parabola on its base).—Multiply the square of the middle diameter by the length and by .4189.

The volume of a parabolic spindle is to that of a cylinder of the same height and diameter as 8 to 15.

*Volume of the middle frustum of a parabolic spindle.*—Add together 8 times the square of the maximum diameter, 3 times the square of the end diameter, and 4 times the product of the diameters. Multiply the sum by the length of the frustum and by .05236.

This rule is applicable for calculating the content of casks of parabolic form.

**Casks.**—*To find the volume of a cask of any form.*—Add together 39 times the square of the bung diameter, 25 times the square of the head diameter, and 26 times the product of the diameters. Multiply the sum by the length, and divide by 31,773 for the content in Imperial gallons, or by 26,470 for U. S. gallons.

This rule was framed by Dr. Hutton, on the supposition that the middle third of the length of the cask was a frustum of a parabolic spindle, and each outer third was a frustum of a cone.

*To find the ullage of a cask,* the quantity of liquor in it when it is not full.

1. For a *lying cask*: Divide the number of wet or dry inches by the bung diameter in inches. If the quotient is less than .5, deduct from it one fourth part of what it wants of .5. If it exceeds .5, add to it one fourth part of the excess above .5. Multiply the remainder or the sum by the whole content of the cask. The product is the quantity of liquor in the cask, in gallons, when the dividend is *wet* inches; or the empty space, if *dry* inches.

2. For a *standing cask*: Divide the number of wet or dry inches by the length of the cask. If the quotient exceeds .5, add to it one tenth of its excess above .5; if less than .5, subtract from it one tenth of what it wants of .5. Multiply the sum or the remainder by the whole content of the cask. The product is the quantity of liquor in the cask, when the dividend is *wet* inches; or the empty space, if *dry* inches.

*Volume of cask* (approximate) U. S. gallons = square of mean diam.  $\times$  length in inches  $\times$  .0034. Mean diam. = half the sum of the bung and head diams.

**Volume of an irregular solid.**—Suppose it divided into parts, resembling prisms or other bodies measurable by preceding rules. Find the content of each part; the sum of the contents is the cubic contents of the solid.

The content of a small part is found nearly by multiplying half the sum of the areas of each end by the perpendicular distance between them.

The contents of small irregular solids may sometimes be found by immersing them under water in a prismatic or cylindrical vessel, and observing the amount by which the level of the water descends when the solid is withdrawn. The sectional area of the vessel being multiplied by the descent of the level gives the cubic contents.

Or, weigh the solid in air and in water; the difference is the weight of water it displaces. Divide the weight in pounds by 62.4 to obtain volume in cubic feet, or multiply it by 27.7 to obtain the volume in cubic inches.

When the solid is very large and a great degree of accuracy is not requisite, measure its length, breadth, and depth in several different places, and take the mean of the measurement for each dimension, and multiply the three means together.

When the surface of the solid is very extensive it is better to divide it into triangles, to find the area of each triangle, and to multiply it by the mean depth of the triangle for the contents of each triangular portion; the contents of the triangular sections are to be added together.

The mean depth of a triangular section is obtained by measuring the depth at each angle, adding together the three measurements, and taking one third of the sum.

## PLANE TRIGONOMETRY.

### Trigonometrical Functions.

Every triangle has six parts—three angles and three sides. When any three of these parts are given, provided one of them is a side, the other parts may be determined. By the *solution* of a triangle is meant the determination of the unknown parts of a triangle when certain parts are given.

The *complement* of an angle or arc is what remains after subtracting the angle or arc from  $90^\circ$ .

In general, if we represent any arc by  $A$ , its complement is  $90^\circ - A$ . Hence the complement of an arc that exceeds  $90^\circ$  is negative.

Since the two acute angles of a right-angled triangle are together equal to a right angle, each of them is the complement of the other.

The *supplement* of an angle or arc is what remains after subtracting the angle or arc from  $180^\circ$ . If  $A$  is an arc its supplement is  $180^\circ - A$ . The supplement of an arc that exceeds  $180^\circ$  is negative.

The *sum of the three angles of a triangle is equal to  $180^\circ$* . Either angle is the supplement of the other two. In a right-angled triangle, the right angle being equal to  $90^\circ$ , each of the acute angles is the complement of the other.

*In all right-angled triangles having the same acute angle, the sides have to each other the same ratio.* These ratios have received special names, as follows:

If  $A$  is one of the acute angles,  $a$  the opposite side,  $b$  the adjacent side, and  $c$  the hypotenuse.

**The sine** of the angle  $A$  is the quotient of the opposite side divided by the hypotenuse.  $\text{Sin. } A = \frac{a}{c}$ .

**The tangent** of the angle  $A$  is the quotient of the opposite side divided by the adjacent side.  $\text{Tang. } A = \frac{a}{b}$ .

**The secant** of the angle  $A$  is the quotient of the hypotenuse divided by the adjacent side.  $\text{Sec. } A = \frac{c}{b}$ .

**The cosine, cotangent, and cosecant** of an angle are respectively the sine, tangent, and secant of the complement of that angle. The terms sine, cosine, etc., are called trigonometrical functions.

In a circle whose radius is unity, **the sine** of an arc, or of the angle at the centre measured by that arc, is the perpendicular let fall from one extremity of the arc upon the diameter passing through the other extremity.

**The tangent** of an arc is the line which touches the circle at one extremity of the arc, and is limited by the diameter (produced) passing through the other extremity.

**The secant** of an arc is that part of the produced diameter which is intercepted between the centre and the tangent.

**The versed sine** of an arc is that part of the diameter intercepted between the extremity of the arc and the foot of the sine.

In a circle whose radius is not unity, the trigonometric functions of an arc will be equal to the lines here defined, divided by the radius of the circle.

If  $IC A$  (Fig. 70) is an angle in the first quadrant, and  $CF =$  radius,

$$\text{The sine of the angle} = \frac{FG}{\text{Rad.}} \quad \text{Cos} = \frac{CG}{\text{Rad.}} = \frac{KF}{\text{Rad.}}$$

$$\text{Tang.} = \frac{IA}{\text{Rad.}} \quad \text{Secant} = \frac{CI}{\text{Rad.}} \quad \text{Cot.} = \frac{DL}{\text{Rad.}}$$

$$\text{Cosec.} = \frac{CL}{\text{Rad.}} \quad \text{Versin.} = \frac{GA}{\text{Rad.}}$$

If radius is 1, then Rad. in the denominator is omitted, and sine =  $FG$ , etc.

*The sine of an arc = half the chord of twice the arc.*

The sine of the supplement of the arc is the same as that of the arc itself. Sine of arc  $BDF = FG = \text{sin arc } FA$ .

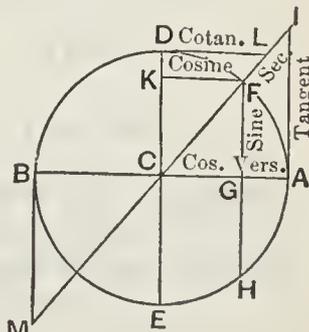

FIG. 70.

The tangent of the supplement is equal to the tangent of the arc, but with a contrary sign.  $\text{Tang. } B D F = B M$ .

The secant of the supplement is equal to the secant of the arc, but with a contrary sign.  $\text{Sec. } B D F = C M$ .

**Signs of the functions in the four quadrants.**—If we divide a circle into four quadrants by a vertical and a horizontal diameter, the upper right-hand quadrant is called the first, the upper left the second, the lower left the third, and the lower right the fourth. The signs of the functions in the four quadrants are as follows:

	First quad.	Second quad.	Third quad.	Fourth quad.
Sine and cosecant,	+	+	−	−
Cosine and secant,	+	−	−	+
Tangent and cotangent,	+	−	+	−

The values of the functions are as follows for the angles specified:

Angle	0°	30°	45°	60°	90°	120°	135°	150°	180°	270°	360°
Sine	0	$\frac{1}{2}$	$\frac{1}{\sqrt{2}}$	$\frac{\sqrt{3}}{2}$	1	$\frac{\sqrt{3}}{2}$	$\frac{1}{\sqrt{2}}$	$\frac{1}{2}$	0	−1	0
Cosine	1	$\frac{\sqrt{3}}{2}$	$\frac{1}{\sqrt{2}}$	$\frac{1}{2}$	0	$-\frac{1}{2}$	$-\frac{1}{\sqrt{2}}$	$-\frac{\sqrt{3}}{2}$	−1	0	1
Tangent	0	$\frac{1}{\sqrt{3}}$	1	$\sqrt{3}$	$\infty$	$-\sqrt{3}$	−1	$-\frac{1}{\sqrt{3}}$	0	$\infty$	0
Cotangent	$\infty$	$\sqrt{3}$	1	$\frac{1}{\sqrt{3}}$	0	$-\frac{1}{\sqrt{3}}$	−1	$-\sqrt{3}$	$\infty$	0	$\infty$
Secant	1	$\frac{2}{\sqrt{3}}$	$\sqrt{2}$	2	$\infty$	−2	$-\sqrt{2}$	$-\frac{2}{\sqrt{3}}$	−1	$\infty$	1
Cosecant	$\infty$	2	$\sqrt{2}$	$\frac{2}{\sqrt{3}}$	1	$\frac{2}{\sqrt{3}}$	$\sqrt{2}$	2	$\infty$	−1	$\infty$
Versed sine	0	$\frac{2 - \sqrt{3}}{2}$	$\frac{\sqrt{2} - 1}{\sqrt{2}}$	$\frac{1}{2}$	1	$\frac{3}{2}$	$\frac{\sqrt{2} + 1}{\sqrt{2}}$	$\frac{2 + \sqrt{3}}{2}$	2	1	0

**TRIGONOMETRICAL FORMULÆ.**

The following relations are deduced from the properties of similar triangles (Radius = 1):

$$\cos A : \sin A :: 1 : \tan A, \text{ whence } \tan A = \frac{\sin A}{\cos A};$$

$$\sin A : \cos A :: 1 : \cot A, \text{ " } \cot A = \frac{\cos A}{\sin A};$$

$$\cos A : 1 :: 1 : \sec A, \text{ " } \sec A = \frac{1}{\cos A};$$

$$\sin A : 1 :: 1 : \text{cosec } A, \text{ " } \text{cosec } A = \frac{1}{\sin A};$$

$$\tan A : 1 :: 1 : \cot A \text{ " } \cot A = \frac{1}{\tan A};$$

The sum of the square of the sine of an arc and the square of its cosine equals unity.  $\sin^2 A + \cos^2 A = 1$ .

Also,  $1 + \tan^2 A = \sec^2 A; \quad 1 + \cot^2 A = \text{cosec}^2 A$ .

**Functions of the sum and difference of two angles:**

Let the two angles be denoted by  $A$  and  $B$ , their sum  $A + B = C$ , and their difference  $A - B$  by  $D$ .

$$\sin(A + B) = \sin A \cos B + \cos A \sin B; \quad \dots \dots (1)$$

$$\cos(A + B) = \cos A \cos B - \sin A \sin B; \dots (2)$$

$$\sin(A - B) = \sin A \cos B - \cos A \sin B; \dots (3)$$

$$\cos(A - B) = \cos A \cos B + \sin A \sin B. \dots (4)$$

From these four formulæ by addition and subtraction we obtain

$$\sin(A + B) + \sin(A - B) = 2 \sin A \cos B; \dots (5)$$

$$\sin(A + B) - \sin(A - B) = 2 \cos A \sin B; \dots (6)$$

$$\cos(A + B) + \cos(A - B) = 2 \cos A \cos B; \dots (7)$$

$$\cos(A - B) - \cos(A + B) = 2 \sin A \sin B. \dots (8)$$

If we put  $A + B = C$ , and  $A - B = D$ , then  $A = \frac{1}{2}(C + D)$  and  $B = \frac{1}{2}(C - D)$ , and we have

$$\sin C + \sin D = 2 \sin \frac{1}{2}(C + D) \cos \frac{1}{2}(C - D); \dots (9)$$

$$\sin C - \sin D = 2 \cos \frac{1}{2}(C + D) \sin \frac{1}{2}(C - D); \dots (10)$$

$$\cos C + \cos D = 2 \cos \frac{1}{2}(C + D) \cos \frac{1}{2}(C - D); \dots (11)$$

$$\cos D - \cos C = 2 \sin \frac{1}{2}(C + D) \sin \frac{1}{2}(C - D). \dots (12)$$

Equation (9) may be enunciated thus: The sum of the sines of any two angles is equal to twice the sine of half the sum of the angles multiplied by the cosine of half their difference. These formulæ enable us to transform a sum or difference into a product.

The sum of the sines of two angles is to their difference as the tangent of half the sum of those angles is to the tangent of half their difference.

$$\frac{\sin A + \sin B}{\sin A - \sin B} = \frac{2 \sin \frac{1}{2}(A + B) \cos \frac{1}{2}(A - B)}{2 \cos \frac{1}{2}(A + B) \sin \frac{1}{2}(A - B)} = \frac{\tan \frac{1}{2}(A + B)}{\tan \frac{1}{2}(A - B)}. \quad (13)$$

The sum of the cosines of two angles is to their difference as the cotangent of half the sum of those angles is to the tangent of half their difference.

$$\frac{\cos A + \cos B}{\cos B - \cos A} = \frac{2 \cos \frac{1}{2}(A + B) \cos \frac{1}{2}(A - B)}{2 \sin \frac{1}{2}(A + B) \sin \frac{1}{2}(A - B)} = \frac{\cot \frac{1}{2}(A + B)}{\tan \frac{1}{2}(A - B)}. \quad (14)$$

The sine of the sum of two angles is to the sine of their difference as the sum of the tangents of those angles is to the difference of the tangents.

$$\frac{\sin(A + B)}{\sin(A - B)} = \frac{\tan A + \tan B}{\tan A - \tan B}; \dots (15)$$

$\frac{\sin(A + B)}{\cos A \cos B} = \tan A + \tan B;$	$\tan(A + B) = \frac{\tan A + \tan B}{1 - \tan A \tan B};$
$\frac{\sin(A - B)}{\cos A \cos B} = \tan A - \tan B;$	$\tan(A - B) = \frac{\tan A - \tan B}{1 + \tan A \tan B};$
$\frac{\cos(A + B)}{\cos A \cos B} = 1 - \tan A \tan B;$	$\cot(A + B) = \frac{\cot A \cot B - 1}{\cot B + \cot A};$
$\frac{\cos(A - B)}{\cos A \cos B} = 1 + \tan A \tan B;$	$\cot(A - B) = \frac{\cot A \cot B + 1}{\cot B - \cot A}.$

**Functions of twice an angle :**

$\sin 2A = 2 \sin A \cos A;$	$\cos 2A = \cos^2 A - \sin^2 A;$
$\tan 2A = \frac{2 \tan A}{1 - \tan^2 A};$	$\cot 2A = \frac{\cot^2 A - 1}{2 \cot A}.$

**Functions of half an angle :**

$\sin \frac{1}{2}A = \pm \sqrt{\frac{1 - \cos A}{2}};$	$\cos \frac{1}{2}A = \pm \sqrt{\frac{1 + \cos A}{2}};$
$\tan \frac{1}{2}A = \pm \sqrt{\frac{1 - \cos A}{1 + \cos A}};$	$\cot \frac{1}{2}A = \pm \sqrt{\frac{1 + \cos A}{1 - \cos A}}.$

**Solution of Plane Right-angled Triangles.**

Let  $A$  and  $B$  be the two acute angles and  $C$  the right angle, and  $a$ ,  $b$ , and  $c$  the sides opposite these angles, respectively, then we have

$$1. \sin A = \cos B = \frac{a}{c}; \quad 3. \tan A = \cot B = \frac{a}{b};$$

$$2. \cos A = \sin B = \frac{b}{c}; \quad 4. \cot A = \tan B = \frac{b}{a}.$$

1. In any plane right-angled triangle the sine of either of the acute angles is equal to the quotient of the opposite leg divided by the hypotenuse.

2. The cosine of either of the acute angles is equal to the quotient of the adjacent leg divided by the hypotenuse.

3. The tangent of either of the acute angles is equal to the quotient of the opposite leg divided by the adjacent leg.

4. The cotangent of either of the acute angles is equal to the quotient of the adjacent leg divided by the opposite leg.

5. The square of the hypotenuse equals the sum of the squares of the other two sides.

**Solution of Oblique-angled Triangles.**

The following propositions are proved in works on plane trigonometry. In any plane triangle—

*Theorem 1.* The sines of the angles are proportional to the opposite sides.

*Theorem 2.* The sum of any two sides is to their difference as the tangent of half the sum of the opposite angles is to the tangent of half their difference.

*Theorem 3.* If from any angle of a triangle a perpendicular be drawn to the opposite side or base, the whole base will be to the sum of the other two sides as the difference of those two sides is to the difference of the segments of the base.

CASE I. Given two angles and a side, to find the third angle and the other two sides. 1. The third angle =  $180^\circ$  — sum of the two angles. 2. The sides may be found by the following proportion:

The sine of the angle opposite the given side is to the sine of the angle opposite the required side as the given side is to the required side.

CASE II. Given two sides and an angle opposite one of them, to find the third side and the remaining angles.

The side opposite the given angle is to the side opposite the required angle as the sine of the given angle is to the sine of the required angle.

The third angle is found by subtracting the sum of the other two from  $180^\circ$ , and the third side is found as in Case I.

CASE III. Given two sides and the included angle, to find the third side and the remaining angles.

The sum of the required angles is found by subtracting the given angle from  $180^\circ$ . The difference of the required angles is then found by Theorem II. Half the difference added to half the sum gives the greater angle, and half the difference subtracted from half the sum gives the less angle. The third side is then found by Theorem I.

Another method:

Given the sides  $c$ ,  $b$ , and the included angle  $A$ , to find the remaining side  $a$  and the remaining angles  $B$  and  $C$ .

From either of the unknown angles, as  $B$ , draw a perpendicular  $Be$  to the opposite side.

Then

$$Ae = c \cos A, \quad Be = c \sin A, \quad eC = b - Ae, \quad Be \div eC = \tan C.$$

Or, in other words, solve  $Be$ ,  $Ae$  and  $BeC$  as right-angled triangles.

CASE IV. Given the three sides, to find the angles.

Let fall a perpendicular upon the longest side from the opposite angle, dividing the given triangle into two right-angled triangles. The two segments of the base may be found by Theorem III. There will then be given the hypotenuse and one side of a right-angled triangle to find the angles.

For areas of triangles, see Mensuration.

## ANALYTICAL GEOMETRY.

**Analytical geometry** is that branch of Mathematics which has for its object the determination of the forms and magnitudes of geometrical magnitudes by means of analysis.

**Ordinates and abscissas.**—In analytical geometry two intersecting lines  $YY'$ ,  $XX'$  are used as *coördinate axes*,  $XX'$  being the axis of abscissas or axis of  $X$ , and  $YY'$  the axis of ordinates or axis of  $Y$ .  $A$ , the intersection, is called the origin of coördinates. The distance of any point  $P$  from the axis of  $Y$  measured parallel to the axis of  $X$  is called the *abscissa* of the point, as  $AD$  or  $CP$ , Fig. 71. Its distance from the axis of  $X$ , measured parallel to the axis of  $Y$ , is called the *ordinate*, as  $AC$  or  $PD$ . The abscissa and ordinate taken together are called the coördinates of the point  $P$ . The angle of intersection is usually taken as a right angle, in which case the axes of  $X$  and  $Y$  are called *rectangular coördinates*.

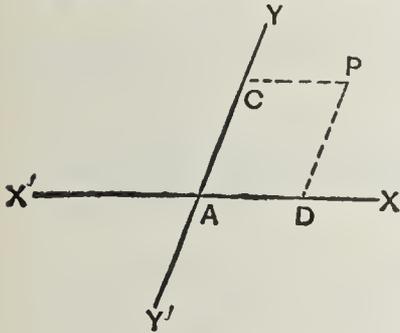

FIG. 71.

The abscissa of a point is designated by the letter  $x$  and the ordinate by  $y$ . The *equations* of a point are the equations which express the distances of the point from the axis. Thus  $x = a$ ,  $y = b$  are the equations of the point  $P$ .

**Equations referred to rectangular coördinates.**—The equation of a line expresses the relation which exists between the coördinates of every point of the line.

Equation of a straight line,  $y = ax \pm b$ , in which  $a$  is the tangent of the angle the line makes with the axis of  $X$ , and  $b$  the distance above  $A$  in which the line cuts the axis of  $Y$ .

Every equation of the first degree between two variables is the equation of a straight line, as  $Ay + Bx + C = 0$ , which can be reduced to the form  $y = ax \pm b$ .

Equation of the distance between two points:

$$D = \sqrt{(x'' - x')^2 + (y'' - y')^2},$$

in which  $x'y'$ ,  $x''y''$  are the coördinates of the two points.

Equation of a line passing through a given point:

$$y - y' = a(x - x'),$$

in which  $x'y'$  are the coördinates of the given point,  $a$ , the tangent of the angle the line makes with the axis of  $x$ , being undetermined, since any number of lines may be drawn through a given point.

Equation of a line passing through two given points:

$$y - y' = \frac{y'' - y'}{x'' - x'}(x - x').$$

Equation of a line parallel to a given line and through a given point:

$$y - y' = a(x - x').$$

Equation of an angle  $V$  included between two given lines:

$$\text{tang } V = \frac{a' - a}{1 + a'a},$$

in which  $a$  and  $a'$  are the tangents of the angles the lines make with the axis of abscissas.

If the lines are at right angles to each other  $\text{tang } V = \infty$ , and

$$1 + a'a = 0.$$

Equation of an intersection of two lines, whose equations are

$$y = ax + b, \quad \text{and} \quad y = a'x + b',$$

$$x = -\frac{b - b'}{a - a'}, \quad \text{and} \quad y = \frac{ab' - a'b}{a - a'}.$$

Equation of a perpendicular from a given point to a given line:

$$y - y' = -\frac{1}{a}(x - x').$$

Equation of the length of the perpendicular  $P$ :

$$P = \frac{y' - ax' - b}{\sqrt{1 + a^2}}.$$

**The circle.**—Equation of a circle, the origin of coördinates being at the centre, and radius =  $R$ :

$$x^2 + y^2 = R^2.$$

If the origin is at the left extremity of the diameter, on the axis of  $X$ :

$$y^2 = 2Rx - x^2.$$

If the origin is at any point, and the coördinates of the centre are  $x'y'$ :

$$(x - x')^2 + (y - y')^2 = R^2.$$

Equation of a tangent to a circle, the coördinates of the point of tangency being  $x''y''$  and the origin at the centre,

$$yy'' + xx'' = R^2.$$

**The ellipse.**—Equation of an ellipse, referred to rectangular coördinates with axis at the centre:

$$A^2y^2 + B^2x^2 = A^2B^2,$$

in which  $A$  is half the transverse axis and  $B$  half the conjugate axis.

Equation of the ellipse when the origin is at the vertex of the transverse axis:

$$y^2 = \frac{B^2}{A^2}(2Ax - x^2).$$

The eccentricity of an ellipse is the distance from the centre to either focus, divided by the semi-transverse axis, or

$$e = \frac{\sqrt{A^2 - B^2}}{A}.$$

The parameter of an ellipse is the double ordinate passing through the focus. It is a third proportional to the transverse axis and its conjugate, or

$$2A : 2B :: 2B : \text{parameter}; \text{ or } \text{parameter} = \frac{2B^2}{A}.$$

Any ordinate of a circle circumscribing an ellipse is to the corresponding ordinate of the ellipse as the semi-transverse axis to the semi-conjugate. Any ordinate of a circle inscribed in an ellipse is to the corresponding ordinate of the ellipse as the semi-conjugate axis to the semi-transverse.

Equation of the tangent to an ellipse, origin of axes at the centre:

$$A^2yy'' + B^2xx'' = A^2B^2,$$

$y''x''$  being the coördinates of the point of tangency.

Equation of the normal, passing through the point of tangency, and perpendicular to the tangent:

$$y - y'' = \frac{A^2y''}{B^2x''}(x - x'').$$

The normal bisects the angle of the two lines drawn from the point of tangency to the foci.

The lines drawn from the foci make equal angles with the tangent.

**The parabola.**—Equation of the parabola referred to rectangular coördinates, the origin being at the vertex of its axis,  $y^2 = 2px$ , in which  $2p$  is the parameter or double ordinate through the focus.

The parameter is a third proportional to any abscissa and its corresponding ordinate, or

$$x : y :: y : 2p.$$

Equation of the tangent:

$$yy'' = p(x + x''),$$

$y''x''$  being coördinates of the point of tangency.

Equation of the normal:

$$y - y'' = -\frac{y''}{p}(x - x'').$$

The sub-normal, or projection of the normal on the axis, is constant, and equal to half the parameter.

The tangent at any point makes equal angles with the axis and with the line drawn from the point of tangency to the focus.

**The hyperbola.**—Equation of the hyperbola referred to rectangular coördinates, origin at the centre:

$$A^2y^2 - B^2x^2 = -A^2B^2,$$

in which  $A$  is the semi-transverse axis and  $B$  the semi-conjugate axis.

Equation when the origin is at the right vertex of the transverse axis:

$$y^2 = \frac{B^2}{A^2}(2Ax + x^2).$$

**Conjugate and equilateral hyperbolas.**—If on the conjugate axis, as a transverse, and a focal distance equal to  $\sqrt{A^2 + B^2}$ , we construct the two branches of a hyperbola, the two hyperbolas thus constructed are called conjugate hyperbolas. If the transverse and conjugate axes are equal, the hyperbolas are called equilateral, in which case  $y^2 - x^2 = -A^2$  when  $A$  is the transverse axis, and  $x^2 - y^2 = -B^2$  when  $B$  is the transverse axis.

The parameter of the transverse axis is a third proportional to the transverse axis and its conjugate.

$$2A : 2B :: 2B : \text{parameter}.$$

The tangent to a hyperbola bisects the angle of the two lines drawn from the point of tangency to the foci.

**The asymptotes of a hyperbola** are the diagonals of the rectangle described on the axes, indefinitely produced in both directions.

In an equilateral hyperbola the asymptotes make equal angles with the transverse axis, and are at right angles to each other.

The asymptotes continually approach the hyperbola, and become tangent to it at an infinite distance from the centre.

**Conic sections.**—Every equation of the second degree between two variables will represent either a circle, an ellipse, a parabola or a hyperbola. These curves are those which are obtained by intersecting the surface of a cone by planes, and for this reason they are called conic sections.

**Logarithmic curve.**—A logarithmic curve is one in which one of the coördinates of any point is the logarithm of the other.

The coördinate axis to which the lines denoting the logarithms are parallel is called the *axis of logarithms*, and the other the axis of numbers. If  $y$  is the axis of logarithms and  $x$  the axis of numbers, the equation of the curve is  $y = \log x$ .

If the base of a system of logarithms is  $a$ , we have  $a^y = x$ , in which  $y$  is the logarithm of  $x$ .

Each system of logarithms will give a different logarithmic curve. If  $y = 0$ ,  $x = 1$ . Hence every logarithmic curve will intersect the axis of numbers at a distance from the origin equal to 1.

## DIFFERENTIAL CALCULUS.

The differential of a variable quantity is the difference between any two of its consecutive values; hence it is indefinitely small. It is expressed by writing  $d$  before the quantity, as  $dx$ , which is read differential of  $x$ .

The term  $\frac{dy}{dx}$  is called the differential coefficient of  $y$  regarded as a function of  $x$ .

The differential of a function is equal to its differential coefficient multiplied by the differential of the independent variable; thus,  $\frac{dy}{dx}dx = dy$ .

The *limit* of a variable quantity is that value to which it continually approaches, so as at last to differ from it by less than any assignable quantity.

The differential coefficient is the limit of the ratio of the increment of the independent variable to the increment of the function.

The differential of a constant quantity is equal to 0.

The differential of a product of a constant by a variable is equal to the constant multiplied by the differential of the variable.

$$\text{If } u = Av, \quad du = Adv.$$

In any curve whose equation is  $y = f(x)$ , the differential coefficient  $\frac{dy}{dx} = \tan a$ ; hence, the rate of increase of the function, or the ascension of the curve at any point, is equal to the tangent of the angle which the tangent line makes with the axis of abscissas.

All the operations of the Differential Calculus comprise but two objects:

1. To find the rate of change in a function when it passes from one state of value to another, consecutive with it.

2. To find the actual change in the function: The rate of change is the differential coefficient, and the actual change the differential.

**Differentials of algebraic functions.**—The differential of the sum or difference of any number of functions, dependent on the same variable, is equal to the sum or difference of their differentials taken separately:

$$\text{If } u = y + z - w, \quad du = dy + dz - dw.$$

The differential of a product of two functions dependent on the same variable is equal to the sum of the products of each by the differential of the other:

$$d(uv) = vdu + udv. \quad \frac{d(uv)}{uv} = \frac{du}{u} + \frac{dv}{v}.$$

The differential of the product of any number of functions is equal to the sum of the products which arise by multiplying the differential of each function by the product of all the others:

$$d(uts) = tsdu + usdt + utds.$$

The differential of a fraction equals the denominator into the differential of the numerator minus the numerator into the differential of the denominator, divided by the square of the denominator:

$$dt = d\left(\frac{u}{v}\right) = \frac{vdu - udv}{v^2}.$$

If the denominator is constant,  $dv = 0$ , and  $dt = \frac{vdu}{v^2} = \frac{du}{v}$ .

If the numerator is constant,  $du = 0$ , and  $dt = -\frac{udv}{v^2}$ .

The differential of the square root of a quantity is equal to the differential of the quantity divided by twice the square root of the quantity:

$$\text{If } v = u^{\frac{1}{2}}, \quad \text{or } v = \sqrt{u}, \quad dv = \frac{du}{2\sqrt{u}}; = \frac{1}{2}u^{-\frac{1}{2}}du.$$

The differential of any power of a function is equal to the exponent multiplied by the function raised to a power less one, multiplied by the differential of the function,  $d(u^n) = nu^{n-1}du$ .

**Formulas for differentiating algebraic functions.**

- |  |  |
|--|--|
| <p>1. <math>d(a) = 0</math>.</p> <p>2. <math>d(ax) = adx</math>.</p> <p>3. <math>d(x + y) = dx + dy</math>.</p> <p>4. <math>d(x - y) = dx - dy</math>.</p> <p>5. <math>d(xy) = xdy + ydx</math>.</p> | <p>6. <math>d\left(\frac{x}{y}\right) = \frac{ydx - xdy}{y^2}</math>.</p> <p>7. <math>d(x^m) = mx^{m-1}dx</math>.</p> <p>8. <math>d(\sqrt{x}) = \frac{dx}{2\sqrt{x}}</math>.</p> <p>9. <math>d\left(x^{-\frac{r}{s}}\right) = -\frac{r}{s}x^{-\frac{r}{s}-1}dx</math>.</p> |
|--|--|

To find the differential of the form  $u = (a + bx^n)^m$ :

Multiply the exponent of the parenthesis into the exponent of the variable within the parenthesis, into the coefficient of the variable, into the binomial raised to a power less 1, into the variable within the parenthesis raised to a power less 1, into the differential of the variable.

$$du = d(a + bx^n)^m = mnb(a + bx^n)^{m-1}x^{n-1}dx.$$

To find the rate of change for a given value of the variable:

Find the differential coefficient, and substitute the value of the variable in the second member of the equation.

**EXAMPLE.**—If  $x$  is the side of a cube and  $u$  its volume,  $u = x^3$ ,  $\frac{du}{dx} = 3x^2$ .

Hence the rate of change in the volume is three times the square of the edge. If the edge is denoted by 1, the rate of change is 3.

*Application.* The coefficient of expansion by heat of the volume of a body is three times the linear coefficient of expansion. Thus if the side of a cube expands .001 inch, its volume expands .003 cubic inch.  $1.001^3 = 1.003003001$ .

**A partial differential coefficient** is the differential coefficient of a function of two or more variables under the supposition that only one of them has changed its value.

A partial differential is the differential of a function of two or more variables under the supposition that only one of them has changed its value.

The total differential of a function of any number of variables is equal to the sum of the partial differentials.

If  $u = f(xy)$ , the partial differentials are  $\frac{du}{dx}dx, \frac{du}{dy}dy$ .

If  $u = x^2 + y^3 - z$ ,  $du = \frac{du}{dx}dx + \frac{du}{dy}dy + \frac{du}{dz}dz; = 2xdx + 3y^2dy - dz$ .

**Integrals.**—An integral is a functional expression derived from a differential. Integration is the operation of finding the primitive function from the differential function. It is indicated by the sign  $\int$ , which is read "the integral of." Thus  $\int 2xdx = x^2$ ; read, the integral of  $2xdx$  equals  $x^2$ .

To integrate an expression of the form  $mx^{m-1}dx$  or  $x^m dx$ , add 1 to the exponent of the variable, and divide by the new exponent and by the differential of the variable:  $\int 3x^2dx = x^3$ . (Applicable in all cases except when  $m = -1$ . For  $\int x^{-1} dx$  see formula 2 page 78.)

The integral of the product of a constant by the differential of a variable is equal to the constant multiplied by the integral of the differential:

$$\int ax^m dx = a \int x^m dx = a \frac{1}{m+1} x^{m+1}.$$

The integral of the algebraic sum of any number of differentials is equal to the algebraic sum of their integrals:

$$du = 2ax^2dx - bydy - z^2dz; \int du = \frac{2}{3}ax^3 - \frac{b}{2}y^2 - \frac{z^3}{3}.$$

Since the differential of a constant is 0, a constant connected with a variable by the sign  $+$  or  $-$  disappears in the differentiation; thus  $d(a + x^m) = dx^m = mx^{m-1}dx$ . Hence in integrating a differential expression we must

annex to the integral obtained a constant represented by  $C$  to compensate for the term which may have been lost in differentiation. Thus if we have  $dy = adx$ ;  $\int dy = a\int dx$ . Integrating,

$$y = ax \pm C.$$

The constant  $C$ , which is added to the first integral, must have such a value as to render the functional equation true for every possible value that may be attributed to the variable. Hence, after having found the first integral equation and added the constant  $C$ , if we then make the variable equal to zero, the value which the function assumes will be the true value of  $C$ .

An indefinite integral is the first integral obtained before the value of the constant  $C$  is determined.

A particular integral is the integral after the value of  $C$  has been found.

A definite integral is the integral corresponding to a given value of the variable.

**Integration between limits.**—Having found the indefinite integral and the particular integral, the next step is to find the definite integral, and then the definite integral between given limits of the variable.

The integral of a function, taken between two limits, indicated by given values of  $x$ , is equal to the difference of the definite integrals corresponding to those limits. The expression

$$\int_{x'}^{x''} dy = a \int dx$$

is read: Integral of the differential of  $y$ , taken between the limits  $x'$  and  $x''$ —the least limit, or the limit corresponding to the subtractive integral, being placed below.

Integrate  $du = 9x^2 dx$  between the limits  $x = 1$  and  $x = 3$ ,  $u$  being equal to 81 when  $x = 0$ .  $\int du = \int 9x^2 dx = 3x^3 + C$ ;  $C = 81$  when  $x = 0$ , then

$$\int_{x=1}^{x=3} du = 3(3)^3 + 81, \text{ minus } 3(1)^3 + 81 = 78.$$

### Integration of particular forms.

To integrate a differential of the form  $du = (a + bx^n)^m x^{n-1} dx$ .

1. If there is a constant factor, place it without the sign of the integral, and omit the power of the variable without the parenthesis and the differential;

2. Augment the exponent of the parenthesis by 1, and then divide this quantity, with the exponent so increased, by the exponent of the parenthesis, into the exponent of the variable within the parenthesis, into the coefficient of the variable. Whence

$$\int du = \frac{(a + bx^n)^{m+1}}{(m+1)nb} = C.$$

The differential of an arc is the hypotenuse of a right-angle triangle of which the base is  $dx$  and the perpendicular  $dy$ .

$$\text{If } z \text{ is an arc, } dz = \sqrt{dx^2 + dy^2} \quad z = \int \sqrt{dx^2 + dy^2}.$$

### Quadrature of a plane figure.

The differential of the area of a plane surface is equal to the ordinate into the differential of the abscissa.

$$ds = ydx.$$

To apply the principle enunciated in the last equation, in finding the area of any particular plane surface:

Find the value of  $y$  in terms of  $x$ , from the equation of the bounding line; substitute this value in the differential equation, and then integrate between the required limits of  $x$ .

**Area of the parabola.**—Find the area of any portion of the common parabola whose equation is

$$y^2 = 2px; \quad \text{whence } y = \sqrt{2px}.$$

Substituting this value of  $y$  in the differential equation  $ds = ydx$  gives

$$\int ds = \int \sqrt{2px} dx = \sqrt{2p} \int x^{\frac{1}{2}} dx = \frac{2\sqrt{2p}}{3} x^{\frac{3}{2}} + C;$$

$$\text{or, } s = \frac{2\sqrt{2px} \times x}{3} = \frac{2}{3} xy + C.$$

If we estimate the area from the principal vertex,  $x = 0$ ,  $y = 0$ , and  $C = 0$ ; and denoting the particular integral by  $s'$ ,  $s' = \frac{2}{3} xy$ .

That is, the area of any portion of the parabola, estimated from the vertex, is equal to  $\frac{2}{3}$  of the rectangle of the abscissa and ordinate of the extreme point. The curve is therefore quadrable.

**Quadrature of surfaces of revolution.**—The differential of a surface of revolution is equal to the circumference of a circle perpendicular to the axis into the differential of the arc of the meridian curve.

$$ds = 2\pi y \sqrt{dx^2 + dy^2};$$

in which  $y$  is the radius of a circle of the bounding surface in a plane perpendicular to the axis of revolution, and  $x$  is the abscissa, or distance of the plane from the origin of coördinate axes.

Therefore, to find the volume of any surface of revolution:

Find the value of  $y$  and  $dy$  from the equation of the meridian curve in terms of  $x$  and  $dx$ , then substitute these values in the differential equation, and integrate between the proper limits of  $x$ .

By application of this rule we may find:

The curved surface of a cylinder equals the product of the circumference of the base into the altitude.

The convex surface of a cone equals the product of the circumference of the base into half the slant height.

The surface of a sphere is equal to the area of four great circles, or equal to the curved surface of the circumscribing cylinder.

**Cubature of volumes of revolution.**—A volume of revolution is a volume generated by the revolution of a plane figure about a fixed line called the axis.

If we denote the volume by  $V$ ,  $dV = \pi y^2 dx$ .

The area of a circle described by any ordinate  $y$  is  $\pi y^2$ ; hence the differential of a volume of revolution is equal to the area of a circle perpendicular to the axis into the differential of the axis.

The differential of a volume generated by the revolution of a plane figure about the axis of  $Y$  is  $\pi x^2 dy$ .

To find the value of  $V$  for any given volume of revolution:

Find the value of  $y^2$  in terms of  $x$  from the equation of the meridian curve, substitute this value in the differential equation, and then integrate between the required limits of  $x$ .

By application of this rule we may find:

The volume of a cylinder is equal to the area of the base multiplied by the altitude.

The volume of a cone is equal to the area of the base into one third the altitude.

The volume of a prolate spheroid and of an oblate spheroid (formed by the revolution of an ellipse around its transverse and its conjugate axis respectively) are each equal to two thirds of the circumscribing cylinder.

If the axes are equal, the spheroid becomes a sphere and its volume =  $\frac{2}{3}\pi R^2 \times D = \frac{1}{6}\pi D^3$ ;  $R$  being radius and  $D$  diameter.

The volume of a paraboloid is equal to half the cylinder having the same base and altitude.

The volume of a pyramid equals the area of the base multiplied by one third the altitude.

**Second, third, etc., differentials.**—The differential coefficient being a function of the independent variable, it may be differentiated, and we thus obtain the second differential coefficient:

$$d\left(\frac{du}{dx}\right) = \frac{d^2u}{dx^2}. \text{ Dividing by } dx, \text{ we have for the second differential coefficient.}$$

cient  $\frac{d^2u}{dx^2}$ , which is read: second differential of  $u$  divided by the square of the differential of  $x$  (or  $dx$  squared).

The third differential coefficient  $\frac{d^3u}{dx^3}$  is read: third differential of  $u$  divided by  $dx$  cubed.

The differentials of the different orders are obtained by multiplying the differential coefficients by the corresponding powers of  $dx$ ; thus  $\frac{d^3u}{dx^3} dx^3 =$  third differential of  $u$ .

**Sign of the first differential coefficient.**—If we have a curve whose equation is  $y = fx$ , referred to rectangular coördinates, the curve will recede from the axis of  $X$  when  $\frac{dy}{dx}$  is positive, and approach the axis when it is negative, when the curve lies within the first angle of the coördinate axes. For all angles and every relation of  $y$  and  $x$  the curve will recede from the axis of  $X$  when the ordinate and first differential coefficient have the same sign, and approach it when they have different signs. If the tangent of the curve becomes parallel to the axis of  $X$  at any point  $\frac{dy}{dx} = 0$ . If the tangent becomes perpendicular to the axis of  $X$  at any point  $\frac{dy}{dx} = \infty$ .

**Sign of the second differential coefficient.**—The second differential coefficient has the same sign as the ordinate when the curve is convex toward the axis of abscissa and a contrary sign when it is concave.

**Maclaurin's Theorem.**—For developing into a series any function of a single variable as  $u = A + Bx + Cx^2 + Dx^3 + Ex^4$ , etc., in which  $A, B, C$ , etc., are independent of  $x$ :

$$u = (u)_{x=0} + \left(\frac{du}{dx}\right)_{x=0} x + \frac{1}{1 \cdot 2} \left(\frac{d^2u}{dx^2}\right)_{x=0} x^2 + \frac{1}{1 \cdot 2 \cdot 3} \left(\frac{d^3u}{dx^3}\right)_{x=0} x^3 + \text{etc.}$$

In applying the formula, omit the expressions  $x = 0$ , although the coefficients are always found under this hypothesis.

EXAMPLES :

$$(a+x)^m = a^m + ma^{m-1}x + \frac{m(m-1)}{1 \cdot 2} a^{m-2}x^2 + \frac{m(m-1)(m-2)}{1 \cdot 2 \cdot 3} a^{m-3}x^3 + \text{etc.}$$

$$\frac{1}{a+x} = \frac{1}{a} - \frac{x}{a^2} + \frac{x^2}{a^3} - \frac{x^3}{a^4} + \dots - \frac{x^n}{a^{n+1}}, \text{ etc.}$$

**Taylor's Theorem.**—For developing into a series any function of the sum or difference of two independent variables, as  $u' = f(x \pm y)$ :

$$u' = u + \frac{du}{dx} y + \frac{d^2u}{dx^2} \frac{y^2}{1 \cdot 2} + \frac{d^3u}{dx^3} \frac{y^3}{1 \cdot 2 \cdot 3} + \text{etc.},$$

in which  $u$  is what  $u'$  becomes when  $y = 0$ ,  $\frac{du}{dx}$  is what  $\frac{du'}{dx}$  becomes when  $y = 0$ , etc.

**Maxima and minima.**—To find the maximum or minimum value of a function of a single variable:

1. Find the first differential coefficient of the function, place it equal to 0, and determine the roots of the equation.

2. Find the second differential coefficient, and substitute each real root, in succession, for the variable in the second member of the equation. Each root which gives a negative result will correspond to a maximum value of the function, and each which gives a positive result will correspond to a minimum value.

EXAMPLE.—To find the value of  $x$  which will render the function  $y$  a maximum or minimum in the equation of the circle,  $y^2 + x^2 = R^2$ ;

$$\frac{dy}{dx} = -\frac{x}{y}; \text{ making } -\frac{x}{y} = 0 \text{ gives } x = 0.$$

The second differential coefficient is:  $\frac{d^2y}{dx^2} = -\frac{x^2 + y^2}{y^3}$ .

When  $x = 0, y = R$ ; hence  $\frac{d^2y}{dx^2} = -\frac{1}{R}$ , which being negative,  $y$  is a maximum for  $R$  positive.

In applying the rule to practical examples we first find an expression for the function which is to be made a maximum or minimum.

2. If in such expression a constant quantity is found as a factor, it may be omitted in the operation; for the product will be a maximum or a minimum when the variable factor is a maximum or a minimum.

3. Any value of the independent variable which renders a function a maximum or a minimum will render any power or root of that function a maximum or minimum; hence we may square both members of an equation to free it of radicals before differentiating.

By these rules we may find:

The maximum rectangle which can be inscribed in a triangle is one whose altitude is half the altitude of the triangle.

The altitude of the maximum cylinder which can be inscribed in a cone is one third the altitude of the cone.

The surface of a cylindrical vessel of a given volume, open at the top, is a minimum when the altitude equals half the diameter.

The altitude of a cylinder inscribed in a sphere when its convex surface is a maximum is  $r\sqrt{2}$ .  $r =$  radius.

The altitude of a cylinder inscribed in a sphere when the volume is a maximum is  $2r \div \sqrt{3}$ .

(For maxima and minima without the calculus see Appendix, p. 1070.)

**Differential of an exponential function.**

$$\text{If } u = a^x. \dots \dots \dots (1)$$

$$\text{then } du = da^x = a^x k dx, \dots \dots \dots (2)$$

in which  $k$  is a constant dependent on  $a$ .

$$\text{The relation between } a \text{ and } k \text{ is } a^{\frac{1}{k}} = e; \text{ whence } a = e^{k}, \dots \dots \dots (3)$$

in which  $e = 2.7182818 \dots$  the base of the Naperian system of logarithms.

**Logarithms.**—The logarithms in the Naperian system are denoted by  $l$ , Nap. log or hyperbolic log, hyp. log, or  $\log_e$ ; and in the common system always by  $\log$ .

$$k = \text{Nap. log } a, \log a = k \log e \dots \dots \dots (4)$$

The common logarithm of  $e, = \log 2.7182818 \dots = .4342945 \dots$  is called the modulus of the common system, and is denoted by  $M$ . Hence, if we have the Naperian logarithm of a number we can find the common logarithm of the same number by multiplying by the modulus. Reciprocally, Nap.  $\log = \text{com. log} \times 2.3025851$ .

If in equation (4) we make  $a = 10$ , we have

$$1 = k \log e, \text{ or } \frac{1}{k} = \log e = M.$$

That is, the modulus of the common system is equal to 1, divided by the Naperian logarithm of the common base.

From equation (2) we have

$$\frac{du}{u} = \frac{da^x}{a^x} = k dx.$$

If we make  $a = 10$ , the base of the common system,  $x = \log u$ , and

$$d(\log u) = dx = \frac{du}{u} \times \frac{1}{k} = \frac{du}{u} \times M.$$

That is, the differential of a common logarithm of a quantity is equal to the differential of the quantity divided by the quantity, into the modulus.

If we make  $a = e$ , the base of the Naperian system,  $x$  becomes the Nape-

rian logarithm of  $u$ , and  $k$  becomes 1 (see equation (3)); hence  $M = 1$ , and

$$d(\text{Nap. log } u) = dx = \frac{du}{a^x}; = \frac{du}{u}.$$

That is, the differential of a Naperian logarithm of a quantity is equal to the differential of the quantity divided by the quantity; and in the Naperian system the modulus is 1.

Since  $k$  is the Naperian logarithm of  $a$ ,  $du = a^x l a dx$ . That is, the differential of a function of the form  $a^x$  is equal to the function, into the Naperian logarithm of the base  $a$ , into the differential of the exponent.

If we have a differential in a fractional form, in which the numerator is the differential of the denominator, the integral is the Naperian logarithm of the denominator. Integrals of fractional differentials of other forms are given below:

**Differential forms which have known integrals; exponential functions.** ( $l = \text{Nap. log.}$ )

$$1. \quad \int a^x l a dx = a^x + C;$$

$$2. \quad \int \frac{dx}{x} = \int dx x^{-1} = lx + C;$$

$$3. \quad \int (xy^{x-1} dy + y^x l y \times dx) = y^x + C;$$

$$4. \quad \int \frac{dx}{\sqrt{x^2 \pm a^2}} = l(x + \sqrt{x^2 \pm a^2}) + C;$$

$$5. \quad \int \frac{dx}{\sqrt{x^2 \pm 2ax}} = l(x \pm a + \sqrt{x^2 \pm 2ax}) + C;$$

$$6. \quad \int \frac{2adx}{a^2 - x^2} = l\left(\frac{a+x}{a-x}\right) + C;$$

$$7. \quad \int \frac{2adx}{x^2 - a^2} = l\left(\frac{x-a}{x+a}\right) + C;$$

$$8. \quad \int \frac{2adx}{x\sqrt{a^2 + x^2}} = l\left(\frac{\sqrt{a^2 + x^2} - a}{\sqrt{a^2 + x^2} + a}\right) + C;$$

$$9. \quad \int \frac{2adx}{x\sqrt{a^2 - x^2}} = l\left(\frac{a - \sqrt{a^2 - x^2}}{a + \sqrt{a^2 - x^2}}\right) + C;$$

$$10. \quad \int \frac{x^{-2} dx}{\sqrt{x + x^{-2}}} = -l\left(\frac{1 + \sqrt{1 + a^2 x^2}}{x}\right) + C.$$

**Circular functions.**—Let  $z$  denote an arc in the first quadrant,  $y$  its sine,  $x$  its cosine,  $v$  its versed sine, and  $t$  its tangent; and the following notation be employed to designate an arc by any one of its functions, viz.,

$\sin^{-1} y$  denotes an arc of which  $y$  is the sine

$\cos^{-1} x$  “ “ “ “ “  $x$  is the cosine,

$\tan^{-1} t$  “ “ “ “ “  $t$  is the tangent

(read "arc whose sine is  $y$ ," etc.),—we have the following differential forms which have known integrals ( $r$  = radius):

$$\int \cos z \, dz = \sin z + C;$$

$$\int -\sin z \, dz = \cos z + C;$$

$$\int \frac{dy}{\sqrt{1-y^2}} = \sin^{-1} y + C;$$

$$\int \frac{-dx}{\sqrt{1-x^2}} = \cos^{-1} x + C;$$

$$\int \frac{dv}{\sqrt{2v-v^2}} = \text{ver-sin}^{-1} v + C;$$

$$\int \frac{dt}{1+t^2} = \tan^{-1} t + C;$$

$$\int \frac{r dy}{\sqrt{r^2-y^2}} = \sin^{-1} \frac{y}{r} + C;$$

$$\int \frac{-r dx}{\sqrt{r^2-x^2}} = \cos^{-1} \frac{x}{r} + C;$$

$$\int \sin z \, dz = \text{ver-sin} z + C;$$

$$\int \frac{dz}{\cos^2 z} = \tan z + C;$$

$$\int \frac{rdv}{\sqrt{2rv-v^2}} = \text{ver-sin}^{-1} v + C;$$

$$\int \frac{r^2 dt}{r^2+t^2} = \tan^{-1} t + C;$$

$$\int \frac{du}{\sqrt{a^2-u^2}} = \sin^{-1} \frac{u}{a} + C;$$

$$\int \frac{-du}{\sqrt{a^2-u^2}} = \cos^{-1} \frac{u}{a} + C;$$

$$\int \frac{du}{\sqrt{2au-u^2}} = \text{ver-sin}^{-1} \frac{u}{a} + C;$$

$$\int \frac{adu}{a^2+u^2} = \tan^{-1} \frac{u}{a} + C.$$

**The cycloid.**—If a circle be rolled along a straight line, any point of the circumference, as  $P$ , will describe a curve which is called a cycloid. The circle is called the generating circle, and  $P$  the generating point.

The transcendental equation of the cycloid is

$$x = \text{ver-sin}^{-1} \frac{y}{r} - \sqrt{2ry - y^2},$$

and the differential equation is  $dx = \frac{y dx}{\sqrt{2ry - y^2}}$ .

The area of the cycloid is equal to three times the area of the generating circle.

The surface described by the arc of a cycloid when revolved about its base is equal to 64 thirds of the generating circle.

The volume of the solid generated by revolving a cycloid about its base is equal to five eighths of the circumscribing cylinder.

**Integral calculus.**—In the integral calculus we have to return from the differential to the function from which it was derived. A number of differential expressions are given above, each of which has a known integral corresponding to it, and which being differentiated, will produce the given differential.

In all classes of functions any differential expression may be integrated when it is reduced to one of the known forms; and the operations of the integral calculus consist mainly in making such transformations of given differential expressions as shall reduce them to equivalent ones whose integrals are known.

For methods of making these transformations reference must be made to the text-books on differential and integral calculus.

**Use of reciprocals.**—Reciprocals may be conveniently used to facilitate computations in long division. Instead of dividing as usual, multiply the dividend by the reciprocal of the divisor. The method is especially useful when many different dividends are required to be divided by the same divisor. In this case find the reciprocal of the divisor, and make a small table of its multiples up to 9 times, and use this as a multiplication-table instead of actually performing the multiplication in each case.

EXAMPLE.—9871 and several other numbers are to be divided by 1638. The reciprocal of 1638 is .000610500.

Multiples of the reciprocal:

1. .0006105
2. .0012210
3. .0018315
4. .0024420
5. .0030525
6. .0036630
7. .0042735
8. .0048840
9. .0054945
10. .0061050

The table of multiples is made by continuous addition of 6105. The tenth line is written to check the accuracy of the addition, but it is not afterwards used.

Operation:

Dividend	9871	
Take from table 1.....		.0006105
	7.....	0.042735
	8.....	00.48840
	9.....	005.4945

Quotient ..... 6.0262455

Correct quotient by direct division ..... 6.0262515

The result will generally be correct to as many figures as there are significant figures in the reciprocal, less one, and the error of the next figure will in general not exceed one. In the above example the reciprocal has six significant figures, 610500, and the result is correct to five places of figures.

**LENGTHS OF CIRCULAR ARCS.**

(Degrees being given. Radius of Circle = 1.)

FORMULA.—Length of arc =  $\frac{3.1415927}{180} \times \text{radius} \times \text{number of degrees.}$

RULE.—Multiply the factor in table for any given number of degrees by the radius.

EXAMPLE.—Given a curve of a radius of 55 feet and an angle of 78° 20'. What is the length of same in feet ?

Factor from table for 78° ..... 1.3613568

Factor from table for 20' ..... .0058178

Factor ..... 1.3671746

1.3671746 × 55 = 75.19 feet.

## AREAS OF THE SEGMENTS OF A CIRCLE.

(Diameter = 1; Rise or Height in parts of Diameter being given.)

RULE FOR USE OF THE TABLE. — Divide the rise or height of the segment by the diameter. Multiply the area in the table corresponding to the quotient thus found by the square of the diameter.

If the segment exceeds a semicircle its area is area of circle — area of segment whose rise is (diam. of circle — rise of given segment)

Given chord and rise, to find diameter. Diam = (square of half chord + rise) + rise The half chord is a mean proportional between the two parts into which the chord divides the diameter which is perpendicular to it.

Rise ÷ Diam.	Area.

To find the capacity of pipes greater than the largest given in the table, look in the table for a pipe of one half the given size, and multiply its capacity by 4; or one of one third its size, and multiply its capacity by 9, etc.

To find the *weight* of water in any of the given sizes multiply the capacity in cubic feet by 62 1/4 or the gallons by 8 1/3, or, if a closer approximation is required, by the weight of a cubic foot of water at the actual temperature in the pipe.

Given the dimensions of a cylinder in inches, to find its capacity in U. S. gallons: Square the diameter, multiply by the length and by .0034. If  $d =$  diameter,  $l =$  length, gallons =  $\frac{d^2 \times .7854 \times l}{231} = .0034d^2l$ .

**CYLINDRICAL VESSELS, TANKS, CISTERNS, ETC.**

**Diameter in Feet and Inches, Area in Square Feet, and U. S. Gallons Capacity for One Foot in Depth.**

$$1 \text{ gallon} = 231 \text{ cubic inches} = \frac{1 \text{ cubic foot}}{7.4805} = 0.13368 \text{ cubic feet.}$$

**NUMBER OF BARRELS (31 1-2 GALLONS) IN  
CISTERNS AND TANKS.**

1 Barrel = 31½ gallons =  $\frac{31.5 \times 231}{1728} = 4.21094$  cubic feet. Reciprocal = .237477.

**LOGARITHMS.**

**Logarithms** (abbreviation *log*).—The log of a number is the exponent of the power to which it is necessary to raise a fixed number to produce the given number. The fixed number is called the *base*. Thus if the base is 10, the log of 1000 is 3, for  $10^3 = 1000$ . There are two systems of logs in general use, the *common*, in which the base is 10, and the *Naperian*, or *hyperbolic*, in which the base is 2.718281828 . . . . The Naperian base is commonly denoted by *e*, as in the equation  $e^y = x$ , in which *y* is the Nap. log of *x*.

In any system of logs, the log of 1 is 0; the log of the base, taken in that system, is 1. In any system the base of which is greater than 1, the logs of all numbers greater than 1 are positive and the logs of all numbers less than 1 are negative.

The modulus of any system is equal to the reciprocal of the Naperian log of the base of that system. The modulus of the Naperian system is 1, that of the common system is .4342945.

The log of a number in any system equals the modulus of that system × the Naperian log of the number.

The *hyperbolic* or *Naperian* log of any number equals the common log × 2.3025851.

Every log consists of two parts, an entire part called the *characteristic*, or *index*, and the decimal part, or *mantissa*. The mantissa only is given in the usual tables of common logs, with the decimal point omitted. The characteristic is found by a simple rule, viz., it is one less than the number of figures to the left of the decimal point in the number whose log is to be found. Thus the characteristic of numbers from 1 to 9.99 + is 0, from 10 to 99.99 + is 1, from 100 to 999 + is 2, from .1 to .99 + is -1, from .01 to .099 + is -2, etc. Thus

log of 2000 is 3.30103;	log of .2 is - 1.30103;
“ “ 200 “ 2.30103;	“ “ .02 “ - 2.30103;
“ “ 20 “ 1.30103;	“ “ .002 “ - 3.30103;
“ “ 2 “ 0.30103;	“ “ .0002 “ - 4.30103.

The minus sign is frequently written above the characteristic thus:  $\log .002 = \bar{3}.30103$ . The characteristic only is negative, the decimal part, or mantissa, being always positive.

When a log consists of a negative index and a positive mantissa, it is usual to write the negative sign over the index, or else to add 10 to the index, and to indicate the subtraction of 10 from the resulting logarithm.

Thus  $\log .2 = \bar{1}.30103$ , and this may be written  $9.30103 - 10$ .

In tables of logarithmic sines, etc., the  $- 10$  is generally omitted, as being understood.

**Rules for use of the table of Logarithms.—To find the log of any whole number.**—For 1 to 100 inclusive the log is given complete in the small table on page 129.

For 100 to 999 inclusive the decimal part of the log is given opposite the given number in the column headed 0 in the table (including the two figures to the left, making six figures). Prefix the characteristic, or index, 2.

For 1000 to 9999 inclusive: The last four figures of the log are found opposite the first three figures of the given number and in the vertical column headed with the fourth figure of the given number; prefix the two figures under column 0, and the index, which is 3.

For numbers over 10,000 having five or more digits: Find the decimal part of the log for the first four digits as above, multiply the difference figure in the last column by the remaining digit or digits, and divide by 10 if there be only one digit more, by 100 if there be two more, and so on; add the quotient to the log of the first four digits and prefix the index, which is 4 if there are five digits, 5 if there are six digits, and so on. The table of proportional parts may be used, as shown below.

**To find the log of a decimal fraction or of a whole number and a decimal.**—First find the log of the quantity as if there were no decimal point, then prefix the index according to rule; the index is one less than the number of figures to the left of the decimal point.

Required log of 3.141593.

	log of	3.141	=	0.497068.	Diff. = 138
From proportional parts		5	=	690	
“ “		09	=	1242	
“ “		003	=	041	
	log	3.141593		0.4971498	

**To find the number corresponding to a given log.**—Find in the table the log nearest to the decimal part of the given log and take the first four digits of the required number from the column N and the top or foot of the column containing the log which is the next less than the given log. To find the 5th and 6th digits subtract the log in the table from the given log, multiply the difference by 100, and divide by the figure in the Diff. column opposite the log; annex the quotient to the four digits already found, and place the decimal point according to the rule; the number of figures to the left of the decimal point is one greater than the index.

Find number corresponding to the log.....	0.497150
Next lowest log in table corresponds to 3141.....	.497068
	Diff. = 82

Tabular diff. = 138;  $82 \div 138 = .59 +$

The index being 0, the number is therefore 3.14159 +.

**To multiply two numbers by the use of logarithms.**—Add together the logs of the two numbers, and find the number whose log is the sum.

**To divide two numbers.**—Subtract the log of the divisor from the log of the dividend, and find the number whose log is the difference.

**To raise a number to any given power.**—Multiply the log of the number by the exponent of the power, and find the number whose log is the product.

**To find any root of a given number.**—Divide the log of the number by the index of the root. The quotient is the log of the root.

**To find the reciprocal of a number.**—Subtract the decimal part of the log of the number from 0, add 1 to the index and change the sign of the index. The result is the log of the reciprocal.

Required the reciprocal of 3.141593.

Log of 3.141593, as found above..... 0.4971498  
 Subtract decimal part from 0 gives..... 0.5028502  
 Add 1 to the index, and changing sign of the index gives.. 1.5028502

which is the log of 0.31831.

**To find the fourth term of a proportion by logarithms.**  
 —Add the logarithms of the second and third terms, and from their sum subtract the logarithm of the first term.

When one logarithm is to be subtracted from another, it may be more convenient to convert the subtraction into an addition, which may be done by first subtracting the given logarithm from 10, adding the difference to the other logarithm, and afterwards rejecting the 10.

The difference between a given logarithm and 10 is called its *arithmetical complement*, or *cologarithm*.

To subtract one logarithm from another is the same as to add its complement and then reject 10 from the result. For  $a - b = 10 - b + a - 10$ .

To work a proportion, then, by logarithms, add the complement of the logarithm of the first term to the logarithms of the second and third terms. The characteristic must afterwards be diminished by 10.

**Example in logarithms with a negative index.**—Solve by logarithms  $\left(\frac{526}{1011}\right)^{2.45}$ , which means divide 526 by 1011 and raise the quotient to the 2.45 power.

log 526 =	2.720986
log 1011 =	3.004751
<hr/>	
log of quotient =	- 1.716235
Multiply by	2.45
	<hr/>
	- 2.581175
	- 2.8 64940
	- 1.43 2470
	<hr/>
	- 1.30 477575 = .20173, Ans.

In multiplying - 1.7 by 5, we say:  $5 \times 7 = 35$ , 3 to carry;  $5 \times -1 = -5$  less + 3 carried = - 2. In adding - 2 + 8 + 3 + 1 carried from previous column, we say:  $1 + 3 + 8 = 12$ , minus 2 = 10, set down 0 and carry 1;  $1 + 4 - 2 = 3$ .

## MATERIALS.

## THE CHEMICAL ELEMENTS.

## The Common Elements (42).

Chemical Symbol.	Name.	Atomic Weight.	Chemical Symbol.	Name.	Atomic Weight.	Chemical Symbol.	Name.	Atomic Weight.
Al	Aluminum	27.1	F	Fluorine	19.	Pd	Palladium	106.
Sb	Antimony	120.4	Au	Gold	197.2	P	Phosphorus	31.
As	Arsenic	75.1	H	Hydrogen	1.01	Pt	Platinum	194.9
Ba	Barium	137.4	I	Iodine	126.8	K	Potassium	39.1
Bi	Bismuth	208.1	Ir	Iridium	193.1	Si	Silicon	28.4
B	Boron	10.9	Fe	Iron	56.	Ag	Silver	107.9
Br	Bromine	79.9	Pb	Lead	206.9	Na	Sodium	23.
Cd	Cadmium	111.9	Li	Lithium	7.03	Sr	Strontium	87.6
Ca	Calcium	40.1	Mg	Magnesium	24.3	S	Sulphur	32.1
C	Carbon	12.	Mn	Manganese	55.	Sn	Tin	119.
Cl	Chlorine	35.4	Hg	Mercury	200.	Ti	Titanium	48.1
Cr	Chromium	52.1	Ni	Nickel	58.7	W	Tungsten	184.8
Co	Cobalt	59.	N	Nitrogen	14.	Va	Vanadium	51.4
Cu	Copper	63.6	O	Oxygen	16.	Zn	Zinc	65.4

The atomic weights of many of the elements vary in the decimal place as given by different authorities. The above are the most recent values referred to O = 16 and H = 1.008. When H is taken as 1, O = 15.879, and the other figures are diminished proportionately. (See *Jour. Am. Chem. Soc.*, March, 1896.)

## The Rare Elements (27).

Beryllium, Be.	Glucinum, G.	Rubidium, Rb.	Thallium, Tl.
Cæsium, Cs.	Indium, In.	Ruthenium, Ru.	Thorium, Th.
Cerium, Ce.	Lanthanum, La.	Samarium, Sm.	Uranium, U.
Didymium, D.	Molybdenum, Mo.	Scandium, Sc.	Ytterbium, Yr.
Erbium, E.	Niobium, Nb.	Selenium, Se.	Yttrium, Y.
Gallium, Ga.	Osmium, Os.	Tantalum, Ta.	Zirconium, Zr.
Germanium, Ge.	Rhodium, R.	Tellurium, Te.	

## SPECIFIC GRAVITY.

The specific gravity of a substance is its weight as compared with the weight of an equal bulk of pure water.

**To find the specific gravity of a substance.**

$W$  = weight of body in air;  $w$  = weight of body submerged in water.

$$\text{Specific gravity} = \frac{W}{W - w}$$

If the substance be lighter than the water, sink it by means of a heavier substance, and deduct the weight of the heavier substance.

Specific-gravity determinations are usually referred to the standard of the weight of water at 62° F., 62.355 lbs. per cubic foot. Some experimenters have used 60° F. as the standard, and others 32° and 39.1° F. There is no general agreement.

Given sp. gr. referred to water at 39.1° F., to reduce it to the standard of 62° F. multiply it by 1.00112.

Given sp. gr. referred to water at 62° F., to find weight per cubic foot multiply by 62.355. Given weight per cubic foot, to find sp. gr. multiply by 0.016037. Given sp. gr., to find weight per cubic inch multiply by .036085.

### Weight and Specific Gravity of Metals.

\* Hard and burned.

† Very pure and soft. The sp. gr. decreases as the carbon is increased.

In the first column of figures the lowest are usually those of cast metals, which are more or less porous; the highest are of metals finely rolled or drawn into wire.

**The Hydrometer.**

The hydrometer is an instrument for determining the density of liquids. It is usually made of glass, and consists of three parts: (1) the upper part, a graduated stem or fine tube of uniform diameter; (2) a bulb, or enlargement of the tube, containing air; and (3) a small bulb at the bottom, containing shot or mercury which causes the instrument to float in a vertical position. The graduations are figures representing either specific gravities, or the numbers of an arbitrary scale, as in Baumé's, Twaddell's, Beck's, and other hydrometers.

There is a tendency to discard all hydrometers with arbitrary scales and to use only those which read in terms of the specific gravity directly.

**Baume's Hydrometer and Specific Gravities Compared.**

**PROPERTIES OF THE USEFUL METALS.**

**Aluminum, Al.**—Atomic weight 27.1. Specific gravity 2.6 to 2.7. The lightest of all the useful metals except magnesium. A soft, ductile, malleable metal, of a white color, approaching silver, but with a bluish cast. Very non-corrosive. Tenacity about one third that of wrought-iron. Formerly a rare metal, but since 1890 its production and use have greatly increased on account of the discovery of cheap processes for reducing it from the ore. Melts at about 1160° F. For further description see Aluminum, under Strength of Materials.

**Antimony (Stibium), Sb.**—At. wt. 120.4. Sp. gr. 6.7 to 6.8. A brittle metal of a bluish-white color and highly crystalline or laminated structure. Melts at 842° F. Heated in the open air it burns with a bluish-white flame. Its chief use is for the manufacture of certain alloys, as type-metal (antimony 1, lead 4), britannia (antimony 1, tin 9), and various anti-friction metals (see Alloys). Cubical expansion by heat from 32° to 212° F., 0.0070. Specific heat .050.

**Bismuth, Bi.**—At. wt. 208.1. Bismuth is of a peculiar light reddish color, highly crystalline, and so brittle that it can readily be pulverized. It melts at 510° F., and boils at about 2300° F. Sp. gr. 9.823 at 54° F., and 10.055 just above the melting-point. Specific heat about .0301 at ordinary temperatures. Coefficient of cubical expansion from 32° to 212°, 0.0040. Conductivity for heat about 1/56 and for electricity only about 1/80 of that of silver. Its tensile strength is about 6400 lbs. per square inch. Bismuth expands in cooling, and Tribe has shown that this expansion does not take place until after solidification. Bismuth is the most diamagnetic element known, a sphere of it being repelled by a magnet.

**Cadmium, Cd.**—At. wt. 112. Sp. gr. 8.6 to 8.7. A bluish-white metal, lustrous, with a fibrous fracture. Melts below 500° F. and volatilizes at about 680° F. It is used as an ingredient in some fusible alloys with lead, tin, and bismuth. Cubical expansion from 32° to 212° F., 0.0094.

**Copper, Cu.**—At. wt. 63.2. Sp. gr. 8.81 to 8.95. Fuses at about 1930° F. Distinguished from all other metals by its reddish color. Very ductile and malleable, and its tenacity is next to iron. Tensile strength 20,000 to 30,000 lbs. per square inch. Heat conductivity 73.6% of that of silver, and superior to that of other metals. Electric conductivity equal to that of gold and silver. Expansion by heat from 32° to 212° F., 0.0051 of its volume. Specific heat .093. (See Copper under Strength of Materials; also Alloys.)

**Gold (Aurum), Au.**—At. wt. 197.2. Sp. gr., when pure and pressed in a die, 19.34. Melts at about 1915° F. The most malleable and ductile of all metals. One ounce Troy may be beaten so as to cover 160 sq. ft. of surface. The average thickness of gold leaf is 1/282000 of an inch, or 100 sq. ft. per ounce. One grain may be drawn into a wire 500 ft. in length. The ductility is destroyed by the presence of 1/2000 part of lead, bismuth, or antimony. Gold is hardened by the addition of silver or of copper. In U. S. gold coin there are 90 parts gold and 10 parts of alloy, which is chiefly copper with a little silver. By jewelers the fineness of gold is expressed in carats, pure gold being 24 carats, three fourths fine 18 carats, etc.

**Iridium.**—Iridium is one of the rarer metals. It has a white lustre, resembling that of steel; its hardness is about equal to that of the ruby; in the cold it is quite brittle, but at a white heat it is somewhat malleable. It is one of the heaviest of metals, having a specific gravity of 22.38. It is extremely infusible and almost absolutely inoxidizable.

For uses of iridium, methods of manufacturing it, etc., see paper by W. D. Dudley on the "Iridium Industry," Trans. A. I. M. E. 1884.

**Iron (Ferrum), Fe.**—At. wt. 56. Sp. gr.: Cast, 6.85 to 7.48; Wrought, 7.4 to 7.9. Pure iron is extremely infusible, its melting point being above 3000° F., but its fusibility increases with the addition of carbon, cast iron fusing about 2500° F. Conductivity for heat 11.9, and for electricity 12 to 14.8, silver being 100. Expansion in bulk by heat: cast iron .0033, and wrought iron .0035, from 32° to 212° F. Specific heat: cast iron .1298, wrought iron .1138, steel .1165. Cast iron exposed to continued heat becomes permanently expanded 1½ to 3 per cent of its length. Grate-bars should therefore be allowed about 4 per cent play. (For other properties see Iron and Steel under Strength of Materials.)

**Lead (Plumbum), Pb.**—At. wt. 206.9. Sp. gr. 11.07 to 11.44 by different authorities. Melts at about 625° F., softens and becomes pasty at about 617° F. If broken by a sudden blow when just below the melting-point it is quite brittle and the fracture appears crystalline. Lead is very malleable

and ductile, but its tenacity is such that it can be drawn into wire with great difficulty. Tensile strength, 1600 to 2400 lbs. per square inch. Its elasticity is very low, and the metal flows under very slight strain. Lead dissolves to some extent in pure water, but water containing carbonates or sulphates forms over it a film of insoluble salt which prevents further action.

**Magnesium, Mg.**—At. wt. 24. Sp. gr. 1.69 to 1.75. Silver-white, brilliant, malleable, and ductile. It is one of the lightest of metals, weighing only about two thirds as much as aluminum. In the form of filings, wire, or thin ribbons it is highly combustible, burning with a light of dazzling brilliancy, useful for signal-lights and for flash-lights for photographers. It is nearly non-corrosive, a thin film of carbonate of magnesia forming on exposure to damp air, which protects it from further corrosion. It may be alloyed with aluminum, 5 per cent Mg added to Al giving about as much increase of strength and hardness as 10 per cent of copper. Cubical expansion by heat 0.0083, from 32° to 212° F. Melts at 1200° F. Specific heat .25.

**Manganese, Mn.**—At. wt. 55. Sp. gr. 7 to 8. The pure metal is not used in the arts, but alloys of manganese and iron, called spiegeleisen when containing below 25 per cent of manganese, and ferro-manganese when containing from 25 to 90 per cent, are used in the manufacture of steel. Metallic manganese, when alloyed with iron, oxidizes rapidly in the air, and its function in steel manufacture is to remove the oxygen from the bath of steel whether it exists as oxide of iron or as occluded gas.

**Mercury (Hydrargyrum), Hg.**—At. wt. 199.8. A silver-white metal, liquid at temperatures above -39° F., and boils at 680° F. Unchangeable as gold, silver, and platinum in the atmosphere at ordinary temperatures, but oxidizes to the red oxide when near its boiling-point. Sp. gr.: when liquid 13.58 to 13.59, when frozen 14.4 to 14.5. Easily tarnished by sulphur fumes, also by dust, from which it may be freed by straining through a cloth. No metal except iron or platinum should be allowed to touch mercury. The smallest portions of tin, lead, zinc, and even copper to a less extent, cause it to tarnish and lose its perfect liquidity. Coefficient of cubical expansion from 32° to 212° F. .0182; per deg. .000101.

**Nickel, Ni.**—At. wt. 58.3. Sp. gr. 8.27 to 8.93. A silvery-white metal with a strong lustre, not tarnishing on exposure to the air. Ductile, hard, and as tenacious as iron. It is attracted to the magnet and may be made magnetic like iron. Nickel is very difficult of fusion, melting at about 3000° F. Chiefly used in alloys with copper, as german-silver, nickel-silver, etc., and recently in the manufacture of steel to increase its hardness and strength, also for nickel-plating. Cubical expansion from 32° to 212° F., 0.0038. Specific heat .109.

**Platinum, Pt.**—At. wt. 195. A whitish steel-gray metal, malleable, very ductile, and as unalterable by ordinary agencies as gold. When fused and refined it is as soft as copper. Sp. gr. 21.15. It is fusible only by the oxyhydrogen blowpipe or in strong electric currents. When combined with iridium it forms an alloy of great hardness, which has been used for gun-vents and for standard weights and measures. The most important uses of platinum in the arts are for vessels for chemical laboratories and manufactories, and for the connecting wires in incandescent electric lamps. Cubical expansion from 32° to 212° F., 0.0027, less than that of any other metal except the rare metals, and almost the same as glass.

**Silver (Argentum), Ag.**—At. wt. 107.7. Sp. gr. 10.1 to 11.1, according to condition and purity. It is the whitest of the metals, very malleable and ductile, and in hardness intermediate between gold and copper. Melts at about 1750° F. Specific heat .056. Cubical expansion from 32° to 212° F., 0.0058. As a conductor of electricity it is equal to copper. As a conductor of heat it is superior to all other metals.

**Tin (Stannum) Sn.**—At. wt. 118. Sp. gr. 7.293. White, lustrous, soft, malleable, of little strength, tenacity about 3500 lbs. per square inch. Fuses at 442° F. Not sensibly volatile when melted at ordinary heats. Heat conductivity 14.5, electric conductivity 12.4; silver being 100 in each case. Expansion of volume by heat .0069 from 32° to 212° F. Specific heat .055. Its chief uses are for coating of sheet-iron (called tin plate) and for making alloys with copper and other metals.

**Zinc, Zn.**—At. wt. 65. Sp. gr. 7.14. Melts at 780° F. Volatilizes and burns in the air when melted, with bluish-white fumes of zinc oxide. It is ductile and malleable, but to a much less extent than copper, and its tenacity, about 5000 to 6000 lbs. per square inch, is about one tenth that of wrought iron. It is practically non-corrosive in the atmosphere, a thin film of carbonate of zinc forming upon it. Cubical expansion between 32° and 212° F.,

0.0088. Specific heat .096. Electric conductivity 29, heat conductivity 36, silver being 100. Its principal uses are for coating iron surfaces, called "galvanizing," and for making brass and other alloys.

**Table Showing the Order of**

<b>Malleability.</b>	<b>Ductility.</b>	<b>Tenacity.</b>	<b>Infusibility.</b>
Gold	Platinum	Iron	Platinum
Silver	Silver	Copper	Iron
Aluminum	Iron	Aluminum	Copper
Copper	Copper	Platinum	Gold
Tin	Gold	Silver	Silver
Lead	Aluminum	Zinc	Aluminum
Zinc	Zinc	Gold	Zinc
Platinum	Tin	Tin	Lead
Iron	Lead	Lead	Tin

**WEIGHT OF RODS, BARS, PLATES, TUBES, AND SPHERES OF DIFFERENT MATERIALS.**

Notation: *b* = breadth, *t* = thickness, *s* = side of square, *d* = external diameter, *d*<sub>1</sub> = internal diameter, all in inches.

Sectional areas: of square bars = *s*<sup>2</sup>; of flat bars = *bt*; of round rods = .7854*d*<sup>2</sup>; of tubes = .7854(*d*<sup>2</sup> - *d*<sub>1</sub><sup>2</sup>) = 3.1416(*dt* - *t*<sup>2</sup>).

Volume of 1 foot in length: of square bars = 12*s*<sup>2</sup>; of flat bars = 12*bt*; of round bars = 9.4248*d*<sup>2</sup>; of tubes = 9.4248(*d*<sup>2</sup> - *d*<sub>1</sub><sup>2</sup>) = 37.699(*dt* - *t*<sup>2</sup>), in cu. in.

Weight per foot length = volume × weight per cubic inch of the material.  
Weight of a sphere = diam.<sup>3</sup> × .5236 × weight per cubic inch.

Material.	Specific Gravity.	Weight per cubic foot, lbs.	Weight of Plates 1 inch thick per sq. ft., lbs.	Weight of Square Bars per foot length, lbs.	Weight of Flat Bars per foot length, lbs. Weight per cylindrical in., 1 in. long, = coefficient of *d*<sup>2</sup> in ninth col. ÷ 12.

**For tubes** use the coefficient of *d*<sup>2</sup> in ninth column, as for rods, and multiply it into (*d*<sup>2</sup> - *d*<sub>1</sub><sup>2</sup>); or multiply it by 4(*dt* - *t*<sup>2</sup>).

**For hollow spheres** use the coefficient of *d*<sup>3</sup> in the last column and multiply it into (*d*<sup>3</sup> - *d*<sub>1</sub><sup>3</sup>).

**For hexagons** multiply the weight of square bars by 0.866 (short diam. of hexagon = side of square). **For octagons** multiply by 0.8284.

**MEASURES AND WEIGHTS OF VARIOUS MATERIALS (APPROXIMATE).**

**Brickwork.**—Brickwork is estimated by the thousand, and for various thicknesses of wall runs as follows:

8 $\frac{1}{4}$ -in. wall, or 1 brick in thickness,	14 bricks per superficial feet.
12 $\frac{3}{4}$ " " " 1 $\frac{1}{2}$ " " "	21 " " " "
17 " " " 2 " " "	28 " " " "
21 $\frac{1}{2}$ " " " 2 $\frac{1}{2}$ " " "	35 " " " "

An ordinary brick measures about 8 $\frac{1}{4}$  × 4 × 2 inches, which is equal to 66 cubic inches, or 26.2 bricks to a cubic foot. The average weight is 4 $\frac{1}{2}$  lbs.

**Fuel.**—A bushel of bituminous coal weighs 76 pounds and contains 2683 cubic inches = 1.554 cubic feet. 29.47 bushels = 1 gross ton.

A bushel of coke weighs 40 lbs. (35 to 42 lbs.).

One acre of bituminous coal contains 1600 tons of 2240 lbs. per foot of thickness of coal worked. 15 to 25 per cent must be deducted for waste in mining.

41 to 45 cubic feet bituminous coal when broken down.....	= 1 ton, 2240 lbs.
34 to 41 " " anthracite, prepared for market.....	= 1 ton, 2240 lbs.
123 " " of charcoal.....	= 1 ton, 2240 lbs.
70.9 " " coke.....	= 1 ton, 2240 lbs.
1 cubic foot of anthracite coal (see also page 635).....	= 55 to 66 lbs.
1 " " bituminous " .....	= 50 to 55 lbs.
1 " " Cumberland coal.....	= 53 lbs.
1 " " Cannel coal.....	= 50.3 lbs.
1 " " charcoal (hardwood).....	= 18.5 lbs.
1 " " (pine).....	= 18 lbs.

**A bushel of charcoal.**—In 1881 the American Charcoal-Iron Workers' Association adopted for use in its official publications for the standard bushel of charcoal 2748 cubic inches, or 20 pounds. A ton of charcoal is to be taken at 2000 pounds. This figure of 20 pounds to the bushel was taken as a fair average of different bushels used throughout the country, and it has since been established by law in some States.

**Ores, Earths, etc.**

13 cubic feet of ordinary gold or silver ore, in mine.....	= 1 ton = 2000 lbs.
20 " " broken quartz.....	= 1 ton = 2000 lbs.
18 feet of gravel in bank.....	= 1 ton.
27 cubic feet of gravel when dry.....	= 1 ton.
25 " " sand .....	= 1 ton.
18 " " earth in bank .....	= 1 ton.
27 " " when dry.....	= 1 ton.
17 " " clay.....	= 1 ton.

**Cement.**—English Portland, sp. gr. 1.25 to 1.51, per bbl.... 400 to 430 lbs.  
Rosendale, U. S., a struck bushel ..... 62 to 70 lbs.

**Lime.**—A struck bushel.... 72 to 75 lbs.

**Grain.**—A struck bushel of wheat = 60 lbs.; of corn = 56 lbs.; of oats = 30 lbs.

**Salt.**—A struck bushel of salt, coarse, Syracuse, N. Y. = 56 lbs.; Turk's Island = 76 to 80 lbs.

**Weight of Earth Filling.**

(From Howe's "Retaining Walls.")

	Average weight in lbs. per cubic foot.
Earth, common loam, loose.....	72 to 80
" " shaken.....	82 to 92
" " rammed moderately.....	90 to 100
Gravel.....	90 to 106
Sand.....	90 to 106
Soft flowing mud.....	104 to 120
Sand, perfectly wet.....	118 to 129

Other sizes.—Weight of other sizes can easily be obtained from the above table by means of combinations or divisions. Thus, for example,

- Weight of 12 x 1 1/4 equals weight of 12 x 1 plus weight of 12 x 1/4..... 50.00
- Or, twice weight of 12 x 5/8, as it is twice as thick. .... 50.00
- Weight of 6 x 1 1/8 equals midway weight between 6 x 1 1/8 and 6 x 2..... 38.75
- Weight of 24 x 1 1/8, being twice as wide as 12 x 1 1/8, weighs..... 75.00

**WEIGHT OF IRON AND STEEL SHEETS.****Weights per Square Foot.**

	Iron.	Steel.
Specific gravity .....	7.7	7.854
Weight per cubic foot.....	480.	489.6
"    "    inch.....	.2778	.2833

As there are many gauges in use differing from each other, and even the thicknesses of a certain specified gauge, as the Birmingham, are not assumed the same by all manufacturers, orders for sheets and wires should always state the weight per square foot, or the thickness in thousandths of an inch.

**WEIGHT OF PLATE IRON, PER LINEAL FOOT, IN POUNDS.**  
(Based on 480 lbs. per Cubic Foot. For Steel add 2 per cent.)

Sections B2, B4, B5, and B8 are "special" beams, the others are "standard."

Sectional area = weight in lbs. per ft. ÷ 3.4, or × 0.2941.  
 Weight in lbs. per foot = sectional area × 3.4.

**SIZES AND WEIGHTS OF ROOFING MATERIALS.**

**Corrugated Iron.** (The Cincinnati Corrugating Co.)

SCHEDULE OF WEIGHTS.

U.S. Gauge.	Thickness in decimal parts of an inch. Flat.	Weight per 100 sq. ft. Flat, Painted.	Weight per 100 sq. ft. Corrugated and Painted.	Weight per 100 sq. ft. Corrugated and Galvanized.	Weight in oz. per sq. ft. Flat, Galvanized.
No. 28	.015625	62½ lbs.	70 lbs.	86 lbs.	12½ oz.
No. 26	.01875	75 "	84 "	99 "	14½ "
No. 24	.025	100 "	111 "	127 "	18½ "
No. 22	.03125	125 "	138 "	154 "	22½ "
No. 20	.0375	150 "	165 "	182 "	26½ "
No. 18	.05	200 "	220 "	236 "	34½ "
No. 16	.0625	250 "	275 "	291 "	42½ "

The above table is on the basis of sheets rolled according to the U. S. Standard Sheet-metal Gauge of 1893 (see page 31). It is also on the basis of 2½ × ⅝ in. corrugations.

To estimate the weight per 100 sq. ft. on the roof when lapped one corrugation at sides and 4 in. at ends, add approximately 12½% to the weights per 100 sq. ft., respectively, given above.

Corrugations 2½ in. wide by ½ or ⅝ in. deep are recognized generally as the standard size for both roofing and siding; sheets are manufactured usually in lengths 6, 7, 8, 9, and 10 ft., and have a width of 26½ or 26 in. outside width—ten corrugations,—and will cover 2 ft. when lapped one corrugation at sides.

Ordinary corrugated sheets should have a lap of 1½ or 2 corrugations side-lap for roofing in order to secure water-tight side seams; if the roof is rather steep 1½ corrugations will answer.

Some manufacturers make a special high-edge corrugation on sides of sheets (The Cincinnati Corrugating Co.), and thereby are enabled to secure a water-proof side-lap with one corrugation only, thus saving from 6% to 12% of material to cover a given area.

The usual width of flat sheets used for making the above corrugated material is 28¼ inches.

No. 28 gauge corrugated iron is generally used for applying to wooden buildings; but for applying to iron framework No. 24 gauge or heavier should be adopted.

Few manufacturers are prepared to corrugate heavier than No. 20 gauge, but some have facilities for corrugating as heavy as No. 12 gauge.

Ten feet is the limit in length of corrugated sheets.

Galvanizing sheet iron adds about 2½ oz. to its weight per square foot.

**Corrugated Arches.**

For corrugated curved sheets for floor and ceiling construction in fire-proof buildings, No. 16, 18, or 20 gauge iron is commonly used, and sheets may be curved from 4 to 10 in. rise—the higher the rise the stronger the arch.

By a series of tests it has been demonstrated that corrugated arches give the most satisfactory results with a base length not exceeding 6 ft., and 7 ft. or even less is preferable where great strength is required.

These corrugated arches are usually made with 2½ × ⅝ in. corrugations, and in same width of sheet as above mentioned.

**Terra-Cotta.**

Porous terra-cotta roofing 3" thick weighs 16 lbs. per square foot and 2" thick, 12 lbs. per square foot.

Ceiling made of the same material 2" thick weighs 11 lbs. per square foot.

**Tiles.**

Flat tiles 6¼" × 10½" × ⅝" weigh from 1480 to 1850 lbs. per square of roof (100 square feet), the lap being one-half the length of the tile.

Tiles with grooves and fillets weigh from 740 to 925 lbs. per square of roof.

Pan-tiles 14½" × 10½" laid 10" to the weather weigh 850 lbs. per square.

**Tin Plate—Tinned Sheet Steel.**

The usual sizes for roofing tin are 14" × 20" and 20" × 28". Without allowance for lap or waste, tin roofing weighs from 50 to 62 lbs. per square. Tin on the roof weighs from 62 to 75 lbs. per square.

Roofing plates or terne plates (steel plates coated with an alloy of tin and lead) are made only in IC and IX thicknesses (29 and 27 Birmingham gauge). "Coke" and "charcoal" tin plates, old names used when iron made with coke and charcoal was used for the tinned plate, are still used in the trade, although steel plates have been substituted for iron; a coke plate now commonly meaning one made of Bessemer steel, and a charcoal plate one of open-hearth steel. The thickness of the tin coating on the plates varies with different "brands."

For valuable information on Tin Roofing, see circulars of Merchant & Co., Philadelphia.

The thickness and weight of tin plates were formerly designated in the trade, both in the United States and England, by letters, such as I.C., D.C., I.X., D.X., etc. A new system was introduced in the United States in 1898, known as the "American base-box system." The base-box is a package containing 32,000 square inches of plate. The actual boxes used in the trade contain 60, 120, or 240 sheets, according to the size. The number of square inches in any given box divided by 32,000 is known as the "box ratio." This ratio multiplied by the weight or price of the base-box gives the weight or price of the given box. Thus the ratio of a box of 120 sheets 14 × 20 in. is  $33,600 \div 32,000 = 1.05$ , and the price at \$3.00 base is  $\$3.00 \times 1.05 = \$3.15$ . The following tables are furnished by the American Tin Plate Co., Chicago, Ill.

9 x 18	213	240	14 x 26	89	225
10 x 18	192	.....	16 x 26	78	

As slate is usually laid, the number of square feet of roof covered by one slate can be obtained from the following formula :

$$\frac{\text{width} \times (\text{length} - 3 \text{ inches})}{288} = \text{the number of square feet of roof covered.}$$

Weight of slate of various lengths and thicknesses required for one square of roof :

Length in Inches.	Weight in Pounds per Square for the Thickness.							
	1/8"	3-16"	1/4"	3/8"	1/2"	5/8"	3/4"	1"
12	483	724	967	1450	1936	2419	2902	3872
14	460	688	920	1379	1842	2301	2760	3683
16	445	667	890	1336	1784	2229	2670	3567
18	434	650	869	1303	1740	2174	2607	3480
20	425	637	851	1276	1704	2129	2553	3408
22	418	626	836	1254	1675	2093	2508	3350
24	412	617	825	1238	1653	2066	2478	3306
26	407	610	815	1222	1631	2039	2445	3263

The weights given above are based on the number of slate required for one square of roof, taking the weight of a cubic foot of slate at 175 pounds.

**Pine Shingles.**

Number and weight of pine shingles required to cover one square of roof :

Number of Inches Exposed to Weather.	Number of Shingles per Square of Roof.	Weight in Pounds of Shingle on One-square of Roofs.	Remarks.
4	900	216	The number of shingles per square is for common gable-roofs. For hip-roofs add five per cent. to these figures. The weights per square are based on the number per square.
4 1/2	800	192	
5	720	173	
5 1/2	655	157	
6	600	144	

**WEIGHT OF CAST-IRON PIPES OR COLUMNS.**

**In Lbs. per Lineal Foot.**

Cast iron = 450 lbs. per cubic foot.

**THICKNESS OF CAST-IRON WATER-PIPES.**

P. H. Baermann, in a paper read before the Engineers' Club of Philadelphia in 1882, gave twenty different formulas for determining the thickness of cast-iron pipes under pressure. The formulas are of three classes:

1. Depending upon the diameter only.

2. Those depending upon the diameter and head, and which add a constant.

3. Those depending upon the diameter and head, contain an additive or subtractive term depending upon the diameter, and add a constant.

The more modern formulas are of the third class, and are as follows:

- $t = .00008hd + .01d + .36$ .....Shedd, No. 1.
- $t = .00006hd + .0133d + .296$ .....Warren Foundry, No. 2.
- $t = .000058hd + .0152d + .312$ .....Francis, No. 3.
- $t = .000048hd + .013d + .32$ .....Dupuit, No. 4.
- $t = .00004hd + .1 \sqrt{d} + .15$ .....Box, No. 5.
- $t = .000135hd + .4 - .0011d$ .....Whitman, No. 6.
- $t = .00006(h + 230)d + .333 - .0033d$ .....Fanning, No. 7.
- $t = .00015hd + .25 - .0052d$ .....Meggs, No. 8.

In which  $t$  = thickness in inches,  $h$  = head in feet,  $d$  = diameter in inches.

Rankine, "Civil Engineering," p. 721, says: "Cast-iron pipes should be made of a soft and tough quality of iron. Great attention should be paid to moulding them correctly, so that the thickness may be exactly uniform all round. Each pipe should be tested for air-bubbles and flaws by ringing it with a hammer, and for strength by exposing it to the intended greatest working pressure." The rule for computing the thickness of a pipe

to resist a given working pressure is  $t = \frac{rp}{f}$ , where  $r$  is the radius in inches,  $p$  the pressure in pounds per square inch, and  $f$  the tenacity of the iron per square inch. When  $f = 18000$ , and a factor of safety of 5 is used, the above expressed in terms of  $d$  and  $h$  becomes

$$t = \frac{.5d.433h}{3600} = \frac{dh}{16628} = .00006dh$$

"There are limitations, however, arising from difficulties in casting, and by the strain produced by shocks, which cause the thickness to be made greater than that given by the above formula."

NOTE.—The absolute safe static pressure which may be put upon pipe is given by the formula  $P = \frac{2T}{D} \times \frac{S}{5}$ , in which formula  $P$  is the pressure per square inch;  $T$ , the thickness of the shell;  $S$ , the ultimate strength per square inch of the metal in tension; and  $D$ , the inside diameter of the pipe. In the tables  $S$  is taken as 18000 pounds per square inch, with a working strain of one fifth this amount or 3600 pounds per square inch. The formula for the absolute safe static pressure then is:  $P = \frac{7200T}{D}$ .

It is, however, usual to allow for "water-ram" by increasing the thickness enough to provide for 100 pounds additional static pressure, and, to insure sufficient metal for good casting and for wear and tear, a further increase equal to  $.333 \left(1 - \frac{D}{100}\right)$ .

The expression for the thickness then becomes:

$$T = \frac{(P+100)D}{7200} + .333 \left(1 - \frac{D}{100}\right),$$

and for safe working pressure

$$P = \frac{7200}{D} \left(T - .333 \left(1 - \frac{D}{100}\right)\right) - 100.$$

The additional section provided as above represents an increased value under static pressure for the different sizes of pipe as follows (see table in margin). So that to test the pipes up to one fifth of the ultimate strength of the material, the pressures in the marginal table should be added to the pressure-values given in the table above.

**STANDARD PIPE FLANGES.**

Adopted August, 1894, at a conference of committees of the American Society of Mechanical Engineers, and the Master Steam and Hot Water Fitters' Association, with representatives of leading manufacturers and users of pipe.—Trans. A. S. M. E., xxi. 29. (The standard dimensions given have not yet, 1901, been adopted by some manufacturers on account of their unwillingness to make a change in their patterns.)

The list is divided into two groups; for medium and high pressures, the first ranging up to 75 lbs. per square inch, and the second up to 200 lbs.

Pipe size, inches.	Pipe Thickness, $P + \frac{d}{100} + .333 \left(1 - \frac{d}{100}\right)$ .	Thickness, nearest Fraction, inches.	Stress on Pipe per square inch @ 200 lbs.	Radius of Fillet, inches.	Flange Diameters, inches.	Flange Thicknesses at edge, inches.	Width Flange Face, inches.	Bolt Circle Diameter, inches.	Number of Bolts.	Bolt Diameter, inches.	Bolt Length, inches.	Stress on each Bolt, per square inch at Bottom of Thread @ 200 lbs.

NOTES.—Sizes up to 24 inches are designed for 200 lbs. or less.

Sizes from 24 to 48 inches are divided into two scales, one for 200 lbs., the other for less.

The sizes of bolts given are for high pressure. For medium pressures the diameters are ⅛ in. less for pipes 2 to 20 in. diameter inclusive, and ¼ in. less for larger sizes, except 48-in. pipe, for which the size of bolt is ⅜ in.

When two lines of figures occur under one heading, the single columns are for both medium and high pressures. Beginning with 24 inches, the left-hand columns are for medium and the right-hand lines are for high pressures.

The sudden increase in diameters at 16 inches is due to the possible insertion of wrought-iron pipe, making with a nearly constant width of gasket a greater diameter desirable.

When wrought-iron pipe is used, if thinner flanges than those given are sufficient, it is proposed that bosses be used to bring the nuts up to the standard lengths. This avoids the use of a reinforcement around the pipe.

Figures in the 3d, 4th, 5th, and last columns refer only to pipe for high pressure.

In drilling valve flanges a vertical line parallel to the spindles should be midway between two holes on the upper side of the flanges.

**FLANGE DIMENSIONS, ETC., FOR EXTRA HEAVY PIPE FITTINGS (UP TO 250 LBS. PRESSURE).**

Adopted by a Conference of Manufacturers, June 28, 1901.

Pipe from 1/8" to 1" inclusive is butt-welded, and proved to 300 lbs. per sq. in. Pipe 1 1/4" and larger is lap-welded, and proved to 500 lbs per sq. in.

For discussion of the Briggs Standard of Wrought-iron Pipe Dimensions, see Report of the Committee of the A. S. M. E. in "Standard Pipe and Pipe Threads," 1886. Trans., Vol. VIII, p. 29. The diameter of the bottom of the thread is derived from the formula  $D - (0.05D + 1.9) \times \frac{1}{n}$ , in which  $D$  = outside diameter of the tubes, and  $n$  the number of threads to the inch. The diameter of the top of the thread is derived from the formula  $0.8\frac{1}{n} \times 2 + d$ , or  $1.6\frac{1}{n} + d$ , in which  $d$  is the diameter at the bottom of the thread at the end of the pipe.

The sizes for the diameters at the bottom and top of the thread at the end of the pipe are as follows:

Diam. of Pipe, Nominal.	Diam. at Bottom of Thread.	Diam. at Top of Thread.	Diam. of Pipe, Nominal.	Diam. at Bottom of Thread.	Diam. at Top of Thread.	Diam. of Pipe, Nominal.	Diam. at Bottom of Thread.	Diam. at Top of Thread.
in.	in.	in.	in.	in.	in.	in.	in.	in.

2	2.223	2.339						

Having the taper, length of full-threaded portion, and the sizes at bottom and top of thread at the end of the pipe, as given in the table, taps and dies can be made to secure these points correctly, the length of the imperfect threaded portions on the pipe, and the length the tap is run into the fittings beyond the point at which the size is as given, or, in other words, beyond the end of the pipe, having no effect upon the standard. The angle of the thread is 60°, and it is slightly rounded off at top and bottom, so that, instead of its depth being 0.866 its pitch, as is the case with a full V-thread, it is  $\frac{4}{5}$  the pitch, or equal to  $0.8 \div n$ ,  $n$  being the number of threads per inch.

Taper of conical tube ends, 1 in 32 to axis of tube =  $\frac{3}{4}$  inch to the foot total taper.

In estimating the effective steam-heating or boiler surface of tubes, the surface in contact with air or gases of combustion (whether internal or external to the tubes) is to be taken.

For heating liquids by steam, superheating steam, or transferring heat from one liquid or gas to another, the mean surface of the tubes is to be taken.

To find the square feet of surface,  $S$ , in a tube of a given length,  $L$ , in feet, and diameter,  $d$ , in inches, multiply the length in feet by the diameter in inches and by .2618. Or,  $S = \frac{3.1416dL}{12} = .2618dL$ . For the diameters in the table below, multiply the length in feet by the figures given opposite the diameter.

Inches, Diameter.	Square Feet per Foot Length.	Inches, Diameter.	Square Feet per Foot Length.	Inches, Diameter.	Square Feet per Foot Length.

**BENT AND COILED PIPES.**

(National Pipe Bending Co., New Haven, Conn.)

COILS AND BENDS OF IRON AND STEEL PIPE.

Size of pipe.....Inches	$\frac{1}{4}$	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{3}{4}$	1	$1\frac{1}{4}$	$1\frac{1}{2}$	2	$2\frac{1}{2}$	3
Least outside diameter of coil.....Inches	2	$2\frac{1}{2}$	$3\frac{1}{2}$	$4\frac{1}{2}$	6	8	12	16	24	32

Size of pipe.....Inches	$3\frac{1}{2}$	4	$4\frac{1}{2}$	5	6	7	8	9	10	12
Least outside diameter of coil.....Inches	40	48	52	58	66	80	92	105	130	156

Lengths continuous welded up to 3-in. pipe or coupled as desired.

COILS AND BENDS OF DRAWN BRASS AND COPPER TUBING.

Size of tube, outside diameter.....Inches	$\frac{1}{4}$	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	1	$1\frac{1}{4}$	$1\frac{3}{8}$
Least outside diameter of coil.....Inches	1	$1\frac{1}{2}$	2	$2\frac{1}{2}$	3	4	6	7

Size of tube, outside diameter.....Inches	$1\frac{1}{2}$	$1\frac{5}{8}$	$1\frac{3}{4}$	2	$2\frac{1}{4}$	$2\frac{3}{8}$	$2\frac{1}{2}$	$2\frac{3}{4}$
Least outside diameter of coil.....Inches	8	9	10	12	14	16	18	20

Lengths continuous brazed, soldered, or coupled as desired.

90° BENDS. EXTRA-HEAVY WROUGHT-IRON PIPE.

Diameter of pipe.....Inches	4	$4\frac{1}{2}$	5	6	7	8	9	10	12
Radius.....Inches	22	24	26	30	36	42	48	60	72
Centre to end.....Inches	26	$28\frac{1}{2}$	31	36	43	50	57	70	84

The radii given are for the centre of the pipe. "Centre to end" means the perpendicular distance from the centre of one end of the bent pipe to a plane passing across the other end. Standard iron pipes of sizes 4 to 8 in. are bent to radii 8 in. larger than the radii in the above table; sizes 9 to 12 in. to radii 12 in. larger.

**Welded Solid Drawn-steel Tubes**, imported by P. S. Justice & Co.; Philadelphia, are made in sizes from  $\frac{1}{2}$  to  $4\frac{1}{2}$  in. external diameter, varying by  $\frac{1}{8}$ ths, and with thickness of walls from  $\frac{1}{16}$  to  $\frac{11}{16}$  in. The maximum length is 15 feet.

**WEIGHT OF BRASS, COPPER, AND ZINC TUBING.

**To find the thickness of lead pipe required when the head of water is given.** (Chadwick Lead Works).

RULE.—Multiply the head in feet by size of pipe wanted, expressed decimally, and divide by 750; the quotient will give thickness required, in one-hundredths of an inch.

EXAMPLE.—Required thickness of half-inch pipe for a head of 25 feet.

$$25 \times 0.50 \div 750 = 0.16 \text{ inch.}$$

**COMPOSITION OF VARIOUS GRADES OF ROLLED BRASS, ETC.**

Trade Name.	Copper	Zinc.	Tin.	Lead.	Nickel.
Common high brass.....	61.5	38.5	.....	.....	.....
Yellow metal.....	60	40	.....	.....	.....
Cartridge brass.....	66 $\frac{2}{3}$	33 $\frac{1}{3}$	.....	.....	.....
Low brass.....	80	20	.....	.....	.....
Clock brass.....	60	40	.....	$1\frac{1}{2}$	.....
Drill rod.....	60	40	.....	$1\frac{1}{2}$ to 2	.....
Spring brass.....	66 $\frac{2}{3}$	33 $\frac{1}{3}$	$1\frac{1}{2}$	.....	.....
18 per cent German silver.....	61 $\frac{1}{2}$	20 $\frac{1}{2}$	.....	.....	18

The above table was furnished by the superintendent of a mill in Connecticut in 1894. He says: While each mill has its own proportions for various mixtures, depending upon the purposes for which the product is intended, the figures given are about the average standard. Thus, between cartridge brass with 33 $\frac{1}{3}$  per cent zinc and common high brass with 38 $\frac{1}{2}$  per cent zinc, there are any number of different mixtures known generally as "high brass," or specifically as "spinning brass," "drawing brass," etc., wherein the amount of zinc is dependent upon the amount of scrap used in the mixture, the degree of working to which the metal is to be subjected, etc.

**LIMIT GAUGES FOR IRON FOR SCREW THREADS.**

In adopting the Sellers, or Franklin Institute, or United States Standard, as it is variously called, a difficulty arose from the fact that it is the habit of iron manufacturers to make iron over-size, and as there are no over-size

screws in the Sellers system, if iron is too large it is necessary to cut it away with the dies. So great is this difficulty, that the practice of making taps and dies over-size has become very general. If the Sellers system is adopted it is essential that iron should be obtained of the correct size, or very nearly so. Of course no high degree of precision is possible in rolling iron, and when exact sizes were demanded, the question arose how much allowable variation there should be from the true size. It was proposed to make limit-gauges for inspecting iron with two openings, one larger and the other smaller than the standard size, and then specify that the iron should enter the large end and not enter the small one. The following table of dimensions for the limit-gauges was commended by the Master Car-Builders' Association and adopted by letter ballot in 1883.

Size of Iron.	Size of Large End of Gauge.	Size of Small End of Gauge.	Difference.	Size of Iron.	Size of Large End of Gauge.	Size of Small End of Gauge.	Difference.
$\frac{1}{4}$ in.	0.2550	0.2450	0.010	$\frac{5}{8}$ in.	0.6330	0.6170	0.016

$\frac{1}{2}$	0.5070	0.4930	0.014	$1\frac{1}{8}$	1.1350	1.1150	0.020
9-16	0.5700	0.5550	0.015	$1\frac{1}{4}$	1.2605	1.2395	0.021

Caliper gauges with the above dimensions, and standard reference gauges for testing them, are made by The Pratt & Whitney Co.

### THE MAXIMUM VARIATION IN SIZE OF ROUGH IRON FOR U. S. STANDARD BOLTS.

*Am. Mach.*, May 12, 1892.

By the adoption of the Sellers or U. S. Standard thread taps and dies keep their size much longer in use when flatted in accordance with this system than when made sharp "V," though it has been found advisable in practice in most cases to make the taps of somewhat larger outside diameter than the nominal size, thus carrying the threads further towards the V-shape and giving corresponding clearance to the tops of the threads when in the nuts or tapped holes.

Makers of taps and dies often have calls for taps and dies, U. S. Standard, "for rough iron."

An examination of rough iron will show that much of it is rolled out of round to an amount exceeding the limit of variation in size allowed.

In view of this it may be desirable to know what the extreme variation in iron may be, consistent with the maintenance of U. S. Standard threads, i. e., threads which are standard when measured upon the angles, the only place where it seems advisable to have them fit closely. Mr. Chas. A. Bauer, the general manager of the Warder, Bushnell & Glessner Co., at Springfield, Ohio, in 1884 adopted a plan which may be stated as follows: All bolts, whether cut from rough or finished stock, are standard size at the bottom and at the sides or angles of the threads, the variation for fit of the nut and allowance for wear of taps being made in the machine taps. Nuts are punched with holes of such size as to give 85 per cent of a full thread, experience showing that the metal of wrought nuts will then crowd into the threads of the taps sufficiently to give practically a full thread, while if punched smaller some of the metal will be cut out by the tap at the bottom of the threads, which is of course undesirable. Machine taps are made enough larger than the nominal to bring the tops of the threads up sharp, plus the amount allowed for fit and wear of taps. This allows the iron to be enough above the nominal diameter to bring the threads up full (sharp) at top, while if it is small the only effect is to give a flat at top of threads; neither condition affecting the actual size of the thread at the point at which it is intended to bear. Limit gauges are furnished to the mills, by which the iron is rolled, the maximum size being shown in the third column of the table. The minimum diameter is not given, the tendency in rolling being nearly always to exceed the nominal diameter.

In making the taps the threaded portion is turned to the size given in the eighth column of the table, which gives 6 to 7 thousandths of an inch allowance for it and wear of tap. Just above the threaded portion of the tap a

place is turned to the size given in the ninth column, these sizes being the same as those of the regular U. S. Standard bolt, at the bottom of the thread, plus the amount allowed for fit and wear of tap ; or, in other words,  $d' = \text{U. S. Standard } d + (D' - D)$ . Gauges like the one in the cut, Fig. 72, are furnished for this sizing. In finishing the threads of the tap a tool

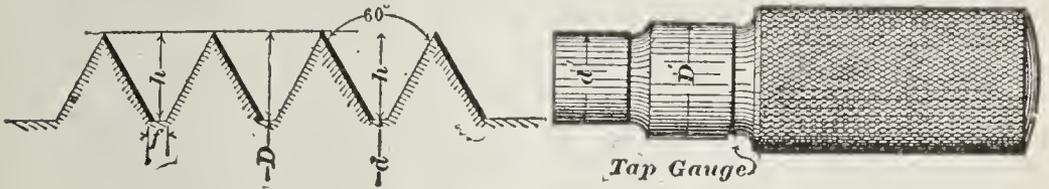

FIG. 72.

is used which has a removable cutter finished accurately to gauge by grinding, this tool being correct U. S. Standard as to angle, and flat at the point. It is fed in and the threads chased until the flat point just touches the portion of the tap which has been turned to size  $d'$ . Care having been taken with the form of the tool, with its grinding on the top face (a fixture being provided for this to insure its being ground properly), and also with the setting of the tool properly in the lathe, the result is that the threads of the tap are correctly sized without further attention.

It is evident that one of the points of advantage of the Sellers system is sacrificed. i.e., instead of the taps being flattened at the top of the threads they are sharp, and are consequently not so durable as they otherwise would be ; but practically this disadvantage is not found to be serious, and is far overbalanced by the greater ease of getting iron within the prescribed limits ; while any rough bolt when reduced in size at the top of the threads, by filing or otherwise, will fit a hole tapped with the U. S. Standard hand taps, thus affording proof that the two kinds of bolts or screws made for the two different kinds of work are practically interchangeable. By this system  $\frac{1}{4}$ " iron can be .005" smaller or .0108" larger than the nominal diameter, or, in other words, it may have a total variation of .0158", while  $1\frac{1}{4}$ " iron can be .0105" smaller or .0309" larger than nominal—a total variation of .0414"—and within these limits it is found practicable to procure the iron.

\* For cast iron. For numbers of twist-drills see p. 29.

Threads are U. S. Standard. Cap screws are threaded 3/4 length up to and including 1" diam. x 4" long, and 1/2 length above. Lengths increase by 1/4" each regular size between the limits given. Lengths of heads, except flat and button, equal diam. of screws.

The angle of the cone of the flat-head screw is 76°, the sides making angles of 52° with the top.

## STANDARD MACHINE SCREWS.

No.	Threads per Inch.	Diam. of Body.	Diam. of Flat Head.	Diam. of Round Head.	Diam. of Filister Head.	Lengths.

40	.007	.00003848	7698.253	.68587		

The above figures on tensile strength are based upon tests made with good charcoal-iron wire from Trenton blooms. The tensile strength of wire made of—  
 Good refined iron is about 15% less,  
 Swedish charcoal iron is about 10% "  
 Mild Bessemer steel is about 10 more,  
 Ordinary crucible steel is about 25 "  
 Special crucible steel is from 30 to 120 "  
 than that of charcoal-iron wire.

**GALVANIZED IRON WIRE FOR TELEGRAPH AND TELEPHONE LINES.**

(Trenton Iron Co.)

**WEIGHT PER MILE-OHM.**—This term is to be understood as distinguishing the *resistance of material* only, and means the weight of such material required per mile to give the resistance of one ohm. To ascertain the mileage resistance of any wire, divide the "weight per mile-ohm" by the weight of the wire per mile. Thus in a grade of Extra Best Best, of which the weight per mile-ohm is 5000, the mileage resistance of No. 6 (weight per mile 525 lbs.) would be about 9½ ohms; and No. 14 steel wire, 6500 lbs. weight per mile-ohm (95 lbs. weight per mile), would show about 69 ohms.

**Sizes of Wire used in Telegraph and Telephone Lines.**

No. 4. Has not been much used until recently; is now used on important lines where the multiplex systems are applied.

No. 5. Little used in the United States.

No. 6. Used for important circuits between cities.

No. 8. Medium size for circuits of 400 miles or less.

No. 9. For similar locations to No. 8, but on somewhat shorter circuits; until lately was the size most largely used in this country.

Nos. 10, 11. For shorter circuits, railway telegraphs, private lines, police and fire-alarm lines, etc.

No. 12. For telephone lines, police and fire-alarm lines, etc.

Nos. 13, 14. For telephone lines and short private lines: steel wire is used most generally in these sizes.

The coating of telegraph wire with zinc as a protection against oxidation is now generally admitted to be the most efficacious method.

The grades of line wire are generally known to the trade as "Extra Best Best" (E. B. B.), "Best Best" (B. B.), and "Steel."

"Extra Best Best" is made of the very best iron, as nearly pure as any commercial iron, soft, tough, uniform, and of very high conductivity, its weight per mile-ohm being about 5000 lbs.

The "Best Best" is of iron, showing in mechanical tests almost as good results as the E. B. B., but not quite as soft, and being somewhat lower in conductivity; weight per mile-ohm about 5700 lbs.

The Trenton "Steel" wire is well suited for telephone or short telegraph lines, and the weight per mile-ohm is about 6500 lbs.

The following are (approximately) the weights per mile of various sizes of galvanized telegraph wire, drawn by Trenton Iron Co.'s gauge:

No.	4,	5,	6,	7,	8,	9,	10,	11,	12,	13,	14.
Lbs.	720,	610,	525,	450,	375,	310,	250,	200,	160,	125,	95.

**TESTS OF TELEGRAPH WIRE.**

The following data are taken from a table given by Mr. Prescott relating to tests of E. B. B. galvanized wire furnished the Western Union Telegraph Co.:

Size of Wire.	Diam. Parts of One Inch.	Weight.		Length. Feet per pound.	Resistance. Temp. 75.8° Fahr.		Ratio of Breaking-Weight to Weight per mile.
		Grains. per foot.	Pounds per mile.		Feet per ohm.	Ohms per mile.	
4	.238	1043.2	886.6	6.00	958	5.51	
5	.220	891.3	673.0	7.85	727	7.26	
6	.203	758.9	572.2	9.20	618	8.54	3.05
7	.180	596.7	449.9	11.70	578	10.86	3.40
8	.165	501.4	378.1	14.00	409	12.92	3.07
9	.148	403.4	304.2	17.4	328	16.10	3.38
10	.134	330.7	249.4	21.2	269	19.60	3.27
11	.120	265.2	200.0	26.4	216	24.42	2.97
12	.109	218.8	165.0	32.0	179	29.60	3.43
14	.083	126.9	95.7	55.2	104	51.00	3.05

**JOINTS IN TELEGRAPH WIRES.**—The fewer the joints in a line the better. All joints should be carefully made and well soldered over, for a bad joint may cause as much resistance to the electric current as several miles of wire.

**TABLE OF DIMENSIONS, WEIGHT, AND RESISTANCE OF PURE COPPER WIRE.**  
(Edison or Circular Mil Gauge.) (See page 30.)

E. S. G. Gauge Number.	Circular Mils.	Maximum Amperes. $\frac{3}{4} \sqrt{\left(\frac{C.M.}{104}\right)^3}$	Diameter in Mils. Mil = .001 in.	Weight. Sp. gr. 8.889.		Length.		Resistance. Legal Ohms at 75° Fahr.		E. S. G. Gauge Number.
				Lbs. per Foot.	Lbs. per Ohm.	Feet per Lb.	Feet per Ohm.	Ohms per Lb.	Ohms per Ft.

In handling this wire the greatest care should be observed to avoid kinks, bends, scratches, or cuts. Joints should be made only with McIntire Connectors.

On account of its conductivity being about five times that of Ex. B. B. Iron Wire, and its breaking strength over three times its weight per mile, copper may be used of which the section is smaller and the weight less than an equivalent iron wire, allowing a greater number of wires to be strung on the poles.

Besides this advantage, the reduction of section materially decreases the electrostatic capacity, while its non-magnetic character lessens the self-induction of the line, both of which features tend to increase the possible speed of signalling in telegraphing, and to give greater clearness of enunciation over telephone lines, especially those of great length.

**INSULATED COPPER WIRE, WEATHERPROOF INSULATION.**

The table is calculated for concentric strands. Rope-laid strands are larger.

**Approximate Rules for the Resistance of Copper Wire.**

—The resistance of any copper wire at 20° C. or 68° F., according to Matthiessen's standard, is  $R = \frac{10.35l}{d^2}$ , in which  $R$  is the resistance in international ohms,  $l$  the length of the wire in feet, and  $d$  its diameter in mils. (1 mil = 1/1000 inch.)

A No 10 Wire, A.W.G., .1019 in. diameter (practically 0.1 in), 1000 ft. in length, has a resistance of 1 ohm at 68° F. and weighs 31.4 lbs.

If a wire of a given length and size by the American or Brown & Sharpe gauge has a certain resistance, a wire of the same length and three numbers higher has twice the resistance, six numbers higher four times the resistance, etc.

Wire gauge, A.W.G. No.....	000	1	4	7	10	13	16	19	22
Relative resistance .....	16	8	4	2	1	1/2	1/4	1/8	1/16
“ section or weight..	1/16	1/8	1/4	1/2	1	2	4	8	16

Approximate rules for resistance at any temperature :

$$R_t = R_0(1 + .004t); \quad R_t = \frac{9.6(1 + .004t)l}{d^2};$$

$R_0$  = resistance at 0°,  $R_t$  = resistance at the temperature  $t$ ° C.,  $l$  = length in feet,  $d$  = diameter in mils. (See Copper Wire Table, p. 1034.)

**GALVANIZED STEEL-WIRE STRAND.**  
**For Smokestack Guys, Signal Strand, etc.**

(J. A. Roebling's Sons Co.)

This strand is composed of 7 wires, twisted together into a single strand.

Diameter.	Weight per 100 Feet.	Estimated Breaking Strength.	Diameter.	Weight per 100 Feet.	Estimated Breaking Strength.	Diameter.	Weight per 100 Feet.	Estimated Breaking Strength.
in.	lbs.	lbs.	in.	lbs.	lbs.	in.	lbs.	lbs.
1/2	51	8,320	9/32	18	2,600	5/32	41/2	700
15/32	48	7,500	17/64	15	2,250	9/64	31/2	525
7/16	37	6,000	1/4	11 1/2	1,750	1/8	2 1/4	375

5/16	21	3,300	3/16	6 1/2	1,000			

For special purposes these strands can be made of 50 to 100 per cent greater tensile strength. When used to run over sheaves or pulleys the use of soft-iron stock is advisable.

**FLEXIBLE STEEL-WIRE CABLES FOR VESSELS.**

(Trenton Iron Co., 1886.)

With numerous disadvantages, the system of working ships' anchors with chain cables is still in vogue. A heavy chain cable contributes to the holding-power of the anchor, and the facility of increasing that resistance by paying out the cable is prized as an advantage. The requisite holding-power is obtained, however, by the combined action of a comparatively light anchor and a correspondingly great mass of chain of little service in proportion to its weight or to the weight of the anchor. If the weight and size of the anchor were increased so as to give the greatest holding-power required, and it were attached by means of a light wire cable, the combined weight of the cable and anchor would be much less than the total weight of the chain and anchor, and the facility of handling would be much greater. English shipbuilders have taken the initiative in this direction, and many of the largest and most serviceable vessels afloat are fitted with steel-wire cables. They have given complete satisfaction.

The Trenton Iron Co.'s cables are made of crucible cast-steel wire, and guaranteed to fulfil Lloyd's requirements. They are composed of 72 wires subdivided into six strands of twelve wires each. In order to obtain great flexibility, hempen centres are introduced in the strands as well as in the completed cable.

**FLEXIBLE STEEL-WIRE HAWSERS.**

These hawsers are extensively used. They are made with six strands of twelve wires each, hempen centres being inserted in the individual strands as well as in the completed rope. The material employed is crucible cast steel, galvanized, and guaranteed to fulfil Lloyd's requirements. They are only one third the weight of hempen hawsers; and are sufficiently pliable to work round any bits to which hempen rope of equivalent strength can be applied.

13-inch tarred Russian hemp hawser weighs about 39 lbs. per fathom.

10-inch white manila hawser weighs about 20 lbs. per fathom.

1 1/8-inch stud chain weighs about 68 lbs. per fathom.

4-inch galvanized steel hawser weighs about 12 lbs. per fathom.

Each of the above named has about the same tensile strength.

**STRENGTH OF PIANO-WIRE.**

The average strength of English piano-wire is given as follows by Webster, Horsfals & Leau:

Numbers in Music-wire Gauge.	Equivalents in Fractions of Inches in Diameters.	Ultimate Tensile Strength in Pounds.	Numbers in Music-wire Gauge.	Equivalents in Fractions of inches in Diameters.	Ultimate Tensile Strength in Pounds.
12	.029	225	18	.041	395
13	.031	250	19	.043	425
14	.033	285	20	.045	500
15	.035	305	21	.047	540
16	.037	340	22	.052	650
17	.039	360			

These strengths range from 300,000 to 340,000 lbs. per sq. in. The composition of this wire is as follows: Carbon, 0.570; silicon, 0.090; sulphur, 0.011; phosphorus, 0.018; manganese, 0.425.

**“PLOUGH”-STEEL WIRE.**

The term “plough,” given in England to steel wire of high quality, was derived from the fact that such wire is used for the construction of ropes used for ploughing purposes. It is to be hoped that the term will not be used in this country, as it tends to confusion of terms. Plough-steel is known here in some steel-works as the quality of plate steel used for the mould-boards of ploughs, for which a very ordinary grade is good enough.

Experiments by Dr. Percy on the English plough-steel (so-called) gave the following results: Specific gravity, 7.814; carbon, 0.828 per cent; manganese, 0.587 per cent; silicon, 0.143 per cent; sulphur, 0.009 per cent; phosphorus, nil; copper, 0.030 per cent. No traces of chromium, titanium, or tungsten were found. The breaking strains of the wire were as follows:

Diameter, inch.....	.093	.132	.159	.191
Pounds per sq. inch.....	344,960	257,600	224,000	201,600

The elongation was only from 0.75 to 1.1 per cent.

**WIRES OF DIFFERENT METALS AND ALLOYS.**

(J. Bucknall Smith's Treatise on Wire.)

**Brass Wire** is commonly composed of an alloy of 1 3/4 to 2 parts of copper to 1 part of zinc. The tensile strength ranges from 20 to 40 tons per square inch, increasing with the percentage of zinc in the alloy.

**German or Nickel Silver**, an alloy of copper, zinc, and nickel, is practically brass whitened by the addition of nickel. It has been drawn into wire as fine as .002" diam.

**Platinum** wire may be drawn into the finest sizes. On account of its high price its use is practically confined to special scientific instruments and electrical appliances in which resistances to high temperature, oxygen, and acids are essential. It expands less than other metals when heated, which property permits its being sealed in glass without fear of cracking. It is therefore used in incandescent electric lamps.

**Phosphor-bronze Wire** contains from 2 to 6 per cent of tin and from 1/20 to 1/8 per cent of phosphorus. The presence of phosphorus is detrimental to electric conductivity.

**"Delta-metal"** wire is made from an alloy of copper, iron, and zinc. Its strength ranges from 45 to 62 tons per square inch. It is used for some kinds of wire rope, also for wire gauze. It is not subject to deposits of verdigris. It has great toughness, even when its tensile strength is over 60 tons per square inch.

**Aluminum Wire.**— Specific gravity .268. Tensile strength only about 10 tons per square inch. It has been drawn as fine as 11,400 yards to the ounce, or .042 grains per yard.

**Aluminum Bronze**, 90 copper, 10 aluminum, has high strength and ductility; is inoxidizable, sonorous. Its electric conductivity is 12.6 per cent.

**Silicon Bronze**, patented in 1882 by L. Weiler of Paris, is made as follows: Fluosilicate of potash, pounded glass, chloride of sodium and calcium, carbonate of soda and lime, are heated in a plumbago crucible, and after the reaction takes place the contents are thrown into the molten bronze to be treated. Silicon-bronze wire has a conductivity of from 40 to 98 per cent of that of copper wire and four times more than that of iron, while its tensile strength is nearly that of steel, or 28 to 55 tons per square inch of section. The conductivity decreases as the tensile strength increases. Wire whose conductivity equals 95 per cent of that of pure copper gives a tensile strength of 28 tons per square inch, but when its conductivity is 34 per cent of pure copper, its strength is 50 tons per square inch. It is being largely used for telegraph wires. It has great resistance to oxidation.

**Ordinary Drawn and Annealed Copper Wire** has a strength of from 15 to 20 tons per square inch.

**SPECIFICATIONS FOR HARD-DRAWN COPPER WIRE.**

The British Post Office authorities require that hard-drawn copper wire supplied to them shall be of the lengths, sizes, weights, strengths, and conductivities as set forth in the annexed table.

Weight per Statute Mile.			Approximate Equivalent Diameter.			Minimum Breaking Weight.	Minimum No. of Twists in 3 Inches.	Maximum Resistance per Mile of Wire (when hard) at 60° Fahr.	Minimum Weight of each Piece (or Coil) of Wire.

**Cable-Traction Ropes.**

According to English practice, cable-traction ropes, of about 3 1/2 in. in circumference, are commonly constructed with six strands of seven or fifteen wires, the lays in the strands varying from, say, 3 in. to 3 1/2 in., and the lays in the ropes from, say, 7 1/2 in. to 9 in. In the United States, however, strands of nineteen wires are generally preferred, as being more flexible; but, on the other hand, the smaller external wires wear out more rapidly. The Market-street Street Railway Company, San Francisco, has used ropes 1 1/4 in. in diameter, composed of six strands of nineteen steel wires, weighing 2 1/2 lbs. per foot, the longest continuous length being 24,125 ft. The Chicago City Railroad Company has employed cables of identical construction, the longest length being 27,700 ft. On the New York and Brooklyn Bridge cable-railway steel ropes of 11,500 ft. long, containing 114 wires, have been used.

**Transmission and Standing Rope.**

With 6 strands of 7 wires each.

**Plough-Steel Rope.**

Wire ropes of very high tensile strength, which are ordinarily called "Plough-steel Ropes," are made of a high grade of crucible steel, which, when put in the form of wire, will bear a strain of from 100 to 150 tons per square inch.

Where it is necessary to use very long or very heavy ropes, a reduction of the dead weight of ropes becomes a matter of serious consideration.

It is advisable to reduce all bends to a minimum, and to use somewhat larger drums or sheaves than are suitable for an ordinary crucible rope having a strength of 60 to 80 tons per square inch. Before using Plough-steel Ropes it is best to have advice on the subject of adaptability.

**Steel Flat Ropes.**

(J. A. Roebling's Sons Co.)

Steel-wire Flat Ropes are composed of a number of strands, alternately twisted to the right and left, laid alongside of each other, and sewed together with soft iron wires. These ropes are used at times in place of round ropes in the shafts of mines. They wind upon themselves on a narrow winding-drum, which takes up less room than one necessary for a round rope. The soft-iron sewing-wires wear out sooner than the steel strands, and then it becomes necessary to sew the rope with new iron wires.

For safe working load allow from one fifth to one seventh of the breaking stress.

**“Lang Lay” Rope.**

In wire rope, as ordinarily made, the component strands are laid up into rope in a direction opposite to that in which the wires are laid into strands; that is, if the wires in the strands are laid from right to left, the strands are laid into rope from left to right. In the “Lang Lay,” sometimes known as ‘Universal Lay,’ the wires are laid into strands and the strands into rope in the same direction; that is, if the wire is laid in the strands from right to left, the strands are also laid into rope from right to left. Its use has been found desirable under certain conditions and for certain purposes, mostly for haulage plants, inclined planes, and street railway cables, although it has also been used for vertical hoists in mines, etc. Its advantages are that

NOTE.—This is an old table, and its authority is uncertain. The figures in the fourth column are probably much too small for durability.

it is somewhat more flexible than rope of the same diameter and composed of the same number of wires laid up in the ordinary manner; and (especially) that owing to the fact that the wires are laid more axially in the rope, longer surfaces of the wire are exposed to wear, and the endurance of the rope is thereby increased. (Trenton Iron Co.)

### Notes on the Use of Wire Rope.

(J. A. Roebling's Sons Co.)

Several kinds of wire rope are manufactured. The most pliable variety contains nineteen wires in the strand, and is generally used for hoisting and running rope. The ropes with twelve wires and seven wires in the strand are stiffer, and are better adapted for standing rope, guys, and rigging. Orders should state the use of the rope, and advice will be given. Ropes are made up to three inches in diameter, upon application.

For safe working load, allow one fifth to one seventh of the ultimate strength, according to speed, so as to get good wear from the rope. When substituting wire rope for hemp rope, it is good economy to allow for the former the same weight per foot which experience has approved for the latter.

Wire rope is as pliable as new hemp rope of the same strength; the former will therefore run over the same-sized sheaves and pulleys as the latter. But the greater the diameter of the sheaves, pulleys, or drums, the longer wire rope will last. The minimum size of drum is given in the table.

Experience has demonstrated that the wear increases with the speed. It is, therefore, better to increase the load than the speed.

Wire rope is manufactured either with a wire or a hemp centre. The latter is more pliable than the former, and will wear better where there is short bending. Orders should specify what kind of centre is wanted.

*Wire rope must not be coiled or uncoiled like hemp rope.*

When mounted on a reel, the latter should be mounted on a spindle or flat turn-table to pay off the rope. When forwarded in a small coil, without reel, roll it over the ground like a wheel, and run off the rope in that way. All untwisting or kinking must be avoided.

To preserve wire rope, apply raw linseed-oil with a piece of sheepskin, wool inside; or mix the oil with equal parts of Spanish brown or lamp-black.

To preserve wire rope under water or under ground, take mineral or vegetable tar, and add one bushel of fresh-slacked lime to one barrel of tar, which will neutralize the acid. Boil it well, and saturate the rope with the hot tar. To give the mixture body, add some sawdust.

The grooves of cast-iron pulleys and sheaves should be filled with well-seasoned blocks of hard wood, set on end, to be renewed when worn out. This end-wood will save wear and increase adhesion. The smaller pulleys or rollers which support the ropes on inclined planes should be constructed on the same plan. When large sheaves run with very great velocity, the grooves should be lined with leather, set on end, or with India rubber. This is done in the case of sheaves used in the *transmission of power* between distant points by means of rope, which frequently runs at the rate of 4000 feet per minute.

Steel ropes are taking the place of iron ropes, where it is a special object to combine lightness with strength.

But in substituting a steel rope for an iron running rope, the object in view should be to gain an increased wear from the rope rather than to reduce the size.

### Locked Wire Rope.

Fig. 74 shows what is known as the Patent Locked Wire Rope, made by the Trenton Iron Co. It is claimed to wear two to three times as long as an

FIG. 74.

ordinary wire rope of equal diameter and of like material. Sizes made are from  $\frac{1}{2}$  to  $1\frac{1}{2}$  inches diameter.

The distance from centre of one link to centre of next is equal to the inside length of link, but in practice 1/32 inch is allowed for weld. This is approximate, and where exactness is required, chain should be made so.

FOR CHAIN SHEAVES.—The diameter, if possible, should be not less than twenty times the diameter of chain used.

EXAMPLE.—For 1-inch chain use 20-inch sheaves.

**WEIGHTS OF LOGS, LUMBER, ETC.**

 17 bricks line a 48-inch circle.

13 1/2-inch straight..... 13 1/2 x 2 1/2 x 6.  
 13 1/2-inch key No. 1 . . . 13 1/2 x 2 1/2 x 6 to 5 inch.  
 90 bricks turn a 12-ft. circle.

13 1/2-inch key No. 2.... 13 1/2 x 2 1/2 x 6 to 4 3/8 inch.  
 52 bricks turn a 6-ft. circle.

Bridge wall, No. 1..... 13 x 6 1/2 x 6.  
 Bridge wall, No. 2..... 13 x 6 1/2 x 3.  
 Mill tile . . . . . 18, 20, or 24 x 6 x 3.

Stock-hole tiles..... 18, 20, or 24 x 9 x 4.  
 18-inch block ..... 18 x 9 x 6.  
 Flat back ..... 9 x 6 x 2 1/2.  
 Flat back arch..... 9 x 6 x 3 1/2 to 2 1/2.  
 22-inch radius, 56 bricks to circle.

Locomotive tile ..... 32 x 10 x 3.  
 34 x 10 x 3.  
 34 x 8 x 3.  
 36 x 8 x 3.  
 40 x 10 x 3.

Tiles, slabs, and blocks, various sizes 12 to 30 inches long, 8 to 30 inches wide, 2 to 6 inches thick.

Cupola brick, 4 and 6 inches high, 4 and 6 inches radial width, to line shells 23 to 66 in diameter.

A 9-inch straight brick weighs 7 lbs. and contains 100 cubic inches. (=120 lbs. per cubic foot. Specific gravity 1.93.)

One cubic foot of wall requires 17 9-inch bricks, one cubic yard requires 460. Where keys, wedges, and other “ shapes ” are used, add 10 per cent in estimating the number required.

One ton of fire-clay should be sufficient to lay 3000 ordinary bricks. To secure the best results, fire-bricks should be laid in the same clay from which they are manufactured. It should be used as a thin paste, and not as mortar. The thinner the joint the better the furnace wall. In ordering bricks the service for which they are required should be stated.

## MAGNESIA BRICKS.

“Foreign Abstracts” of the Institution of Civil Engineers, 1893, gives a paper by C. Bischof on the production of magnesia bricks. The material most in favor at present is the magnesite of Styria, which, although less pure considered as a source of magnesia than the Greek, has the property of fritting at a high temperature without melting. The composition of the two substances, in the natural and burnt states, is as follows:

	Magnesite.	Styrian.	Greek.
Carbonate of magnesia.....	90.0 to 96.0%	94.46%	
“ “ lime.. .. .	0.5 to 2.0	4.49	
“ “ iron.....	3.0 to 6.0	FeO 0.08	
Silica.....	1.0	0.52	
Manganous oxide .....	0.5	Water 0.54	
<b>Burnt Magnesite.</b>			
Magnesia.....	77.6	82.46—95.36	
Lime.....	7.3	0.83—10.92	
Alumina and ferric oxide.....	13.0	0.56— 3.54	
Silica.....	1.2	0.73— 7.98	

At a red heat magnesium carbonate is decomposed into carbonic acid and caustic magnesia, which resembles lime in becoming hydrated and recarbonated when exposed to the air, and possesses a certain plasticity, so that it can be moulded when subjected to a heavy pressure. By long-continued or stronger heating the material becomes dead-burnt, giving a form of magnesia of high density, sp. gr. 3.8, as compared with 3.0 in the plastic form, which is unalterable in the air but devoid of plasticity. A mixture of two volumes of dead-burnt with one of plastic magnesia can be moulded into bricks which contract but little in firing. Other binding materials that have been used are: clay up to 10 or 15 per cent; gas-tar, perfectly freed from water, soda, silica, vinegar as a solution of magnesium acetate which is readily decomposed by heat, and carbolates of alkalies or lime. Among magnesium compounds a weak solution of magnesium chloride may also be used. For setting the bricks lightly burnt, caustic magnesia, with a small proportion of silica to render it less refractory, is recommended. The strength of the bricks may be increased by adding iron, either as oxide or silicate. If a porous product is required, sawdust or starch may be added to the mixture. When dead-burnt magnesia is used alone, soda is said to be the best binding material.

Chemical analysis throws light upon an important point in connection with asbestos, i.e., the cause of the harshness of the fibre of some varieties. Asbestos is principally a hydrous silicate of magnesia, i.e., silicate of magnesia combined with water. When harsh fibre is analyzed it is found to contain less water than the soft fibre. In fibre of very fine quality from Black Lake analysis showed 14.38% of water, while a harsh-fibred sample gave only 11.70%. If soft fibre be heated to a temperature that will drive off a portion of the combined water, there results a substance so brittle that it may be crumbled between thumb and finger. There is evidently some connection between the consistency of the fibre and the amount of water in its composition.

## STRENGTH OF MATERIALS.

**Stress and Strain.**—There is much confusion among writers on strength of materials as to the definition of these terms. An external force applied to a body, so as to pull it apart, is resisted by an internal force, or resistance, and the action of these forces causes a displacement of the molecules, or deformation. By some writers the external force is called a stress, and the internal force a strain; others call the external force a strain, and the internal force a stress: this confusion of terms is not of importance, as the words stress and strain are quite commonly used synonymously, but the use of the word strain to mean molecular displacement, deformation, or distortion, as is the custom of some, is a corruption of the language. See *Engineering News*, June 23, 1892. Definitions by leading authorities are given below.

**Stress.**—A stress is a force which acts in the interior of a body, and resists the external forces which tend to change its shape. A deformation is the amount of change of shape of a body caused by the stress. The word strain is often used as synonymous with stress and sometimes it is also used to designate the deformation. (Merriman.)

The force by which the molecules of a body resist a strain at any point is called the stress at that point.

The summation of the displacements of the molecules of a body for a given point is called the distortion or strain at the point considered. (Burr.)

Stresses are the forces which are applied to bodies to bring into action their elastic and cohesive properties. These forces cause alterations of the forms of the bodies upon which they act. *Strain* is a name given to the kind of alteration produced by the stresses. The distinction between stress and strain is not always observed, one being used for the other. (Wood.)

Stresses are of different kinds, viz.: *tensile, compressive, transverse, torsional, and shearing stresses.*

A *tensile stress*, or pull, is a force tending to elongate a piece. A *compressive stress*, or push, is a force tending to shorten it. A *transverse stress* tends to bend it. A *torsional stress* tends to twist it. A *shearing stress* tends to force one part of it to slide over the adjacent part.

Tensile, compressive, and shearing stresses are called simple stresses. Transverse stress is compounded of tensile and compressive stresses, and torsional of tensile and shearing stresses.

To these five varieties of stresses might be added *tearing stress*, which is either tensile or shearing, but in which the resistance of different portions of the material are brought into play in detail, or one after the other, instead of simultaneously, as in the simple stresses.

**Effects of Stresses.**—The following general laws for cases of simple tension or compression have been established by experiment. (Merriman):

1. When a small stress is applied to a body, a small deformation is produced, and on the removal of the stress the body springs back to its original form. For small stresses, then, materials may be regarded as perfectly elastic.

2. Under small stresses the deformations are approximately proportional to the forces or stresses which produce them, and also approximately proportional to the length of the bar or body.

3. When the stress is great enough a deformation is produced which is partly permanent, that is, the body does not spring back entirely to its original form on removal of the stress. This permanent part is termed a set. In such cases the deformations are not proportional to the stress.

4. When the stress is greater still the deformation rapidly increases and the body finally ruptures.

5. A sudden stress, or shock, is more injurious than a steady stress or than a stress gradually applied.

**Elastic Limit.**—The elastic limit is defined as that point at which the deformations cease to be proportional to the stresses, or, the point at which the rate of stretch (or other deformation) begins to increase. It is also defined as the point at which the first permanent set becomes visible. The last definition is not considered as good as the first, as it is found that with some materials a set occurs with any load, no matter how small, and that with others a set which might be called permanent vanishes with lapse of time, and as it is impossible to get the point of first set without removing

the whole load after each increase of load, which is frequently inconvenient. The elastic limit, defined, however, as the point at which the extensions begin to increase at a higher ratio than the applied stresses, usually corresponds very nearly with the point of first measurable permanent set.

**Apparent Elastic Limit.**—Prof. J. B. Johnson (Materials of Construction, p. 19) defines the "apparent elastic limit" as "the point on the stress diagram [a plotted diagram in which the ordinates represent loads and the abscissas the corresponding elongations] at which the rate of deformation is 50% greater than it is at the origin," [the minimum rate]. An equivalent definition, proposed by the author, is that point at which the modulus of extension (length  $\times$  increment of load per unit of section  $\div$  increment of elongation) is two thirds of the maximum. For steel, with a modulus of elasticity of 30,000,000, this is equivalent to that point at which the increase of elongation in an 8-inch specimen for 1000 lbs. per sq. in. increase of load is 0.0004 in.

**Yield-point.**—The term yield-point has recently been introduced into the literature of the strength of materials. It is defined as that point at which the rate of stretch suddenly increases rapidly. The difference between the elastic limit, strictly defined as the point at which the rate of stretch begins to increase, and the yield-point, at which the rate increases suddenly, may in some cases be considerable. This difference, however, will not be discovered in short test-pieces unless the readings of elongations are

made by an exceedingly fine instrument, as a micrometer reading to  $\frac{1}{10000}$  of an inch. In using a coarser instrument, such as calipers reading to  $\frac{1}{100}$  of an inch, the elastic limit and the yield-point will appear to be simultaneous. Unfortunately for precision of language, the term yield-point was not introduced until long after the term elastic limit had been almost universally adopted to signify the same physical fact which is now defined by the term yield-point, that is, not the point at which the first change in rate, observable only by a microscope, occurs, but that later point (more or less indefinite as to its precise position) at which the increase is great enough to be seen by the naked eye. A most convenient method of determining the point at which a sudden increase of rate of stretch occurs in short specimens, when a testing-machine in which the pulling is done by screws is used, is to note the weight on the beam at the instant that the beam "drops." During the earlier portion of the test, as the extension is steadily increased by the uniform but slow rotation of the screws, the poise is moved steadily along the beam to keep it in equipoise; suddenly a point is reached at which the beam drops, and will not rise until the elongation has been considerably increased by the further rotation of the screws, the advancing of the poise meanwhile being suspended. This point corresponds practically to the point at which the rate of elongation suddenly increases, and to the point at which an appreciable permanent set is first found. It is also the point which has hitherto been called in practice and in text-books the elastic limit, and it will probably continue to be so called, although the use of the newer term "yield-point" for it, and the restriction of the term elastic limit to mean the earlier point at which the rate of stretch begins to increase, as determinable only by micrometric measurements, is more precise and scientific.

In tables of strength of materials hereafter given, the term elastic limit is used in its customary meaning, the point at which the rate of stress has begun to increase, as observable by ordinary instruments or by the drop of the beam. With this definition it is practically synonymous with yield-point.

**Coefficient (or Modulus) of Elasticity.**—This is a term expressing the relation between the amount of extension or compression of a material and the load producing that extension or compression.

It is defined as the load per unit of section divided by the extension per unit of length.

Let  $P$  be the applied load,  $k$  the sectional area of the piece,  $l$  the length of the part extended,  $\lambda$  the amount of the extension, and  $E$  the coefficient of elasticity. Then  $P \div k =$  the load on a unit of section;  $\lambda \div l =$  the elongation of a unit of length.

$$E = \frac{P}{k} \div \frac{\lambda}{l} = \frac{Pl}{k\lambda}.$$

The coefficient of elasticity is sometimes defined as the figure expressing the load which would be necessary to elongate a piece of one square inch section to double its original length, provided the piece would not break, and the ratio of extension to the force producing it remained constant. This definition follows from the formula above given, thus: If  $k =$  one square inch,  $l$  and  $\lambda$  each = one inch, then  $E = P$ .

Within the elastic limit, when the deformations are proportional to the

stresses, the coefficient of elasticity is constant, but beyond the elastic limit it decreases rapidly.

In cast iron there is generally no apparent limit of elasticity, the deformations increasing at a faster rate than the stresses, and a permanent set being produced by small loads. The coefficient of elasticity therefore is not constant during any portion of a test, but grows smaller as the load increases. The same is true in the case of timber. In wrought iron and steel, however, there is a well-defined elastic limit, and the coefficient of elasticity within that limit is nearly constant.

**Resilience, or Work of Resistance of a Material.**—Within the elastic limit, the resistance increasing uniformly from zero stress to the stress at the elastic limit, the work done by a load applied gradually is equal to one half the product of the final stress by the extension or other deformation. Beyond the elastic limit, the extensions increasing more rapidly than the loads, and the strain diagram approximating a parabolic form, the work is approximately equal to two thirds the product of the maximum stress by the extension.

The amount of work required to break a bar, measured usually in inch-pounds, is called its resilience; the work required to strain it to the elastic limit is called its elastic resilience. (See page 270.)

Under a load applied suddenly the momentary elastic distortion is equal to twice that caused by the same load applied gradually.

When a solid material is exposed to percussive stress, as when a weight falls upon a beam transversely, the work of resistance is measured by the product of the weight into the total fall.

**Elevation of Ultimate Resistance and Elastic Limit.**—It was first observed by Prof. R. H. Thurston, and Commander L. A. Beardslee, U. S. N., independently, in 1873, that if wrought iron be subjected to a stress beyond its elastic limit, but not beyond its ultimate resistance, and then allowed to "rest" for a definite interval of time, a considerable increase of elastic limit and ultimate resistance may be experienced. In other words, the application of stress and subsequent "rest" increases the resistance of wrought iron.

This "rest" may be an entire release from stress or a simple holding the test-piece at a given intensity of stress.

Commander Beardslee prepared twelve specimens and subjected them to an intensity of stress equal to the ultimate resistance of the material, without breaking the specimens. These were then allowed to rest, entirely free from stress, from 24 to 30 hours, after which period they were again stressed until broken. The gain in ultimate resistance by the rest was found to vary from 4.4 to 17 per cent.

This elevation of elastic and ultimate resistance appears to be peculiar to iron and steel: it has not been found in other metals.

**Relation of the Elastic Limit to Endurance under Repeated Stresses** (condensed from *Engineering*, August 7, 1891).—When engineers first began to test materials, it was soon recognized that if a specimen was loaded beyond a certain point it did not recover its original dimensions on removing the load, but took a permanent set; this point was called the elastic limit. Since below this point a bar appeared to recover completely its original form and dimensions on removing the load, it appeared obvious that it had not been injured by the load, and hence the working load might be deduced from the elastic limit by using a small factor of safety.

Experience showed, however, that in many cases a bar would not carry safely a stress anywhere near the elastic limit of the material as determined by these experiments, and the whole theory of any connection between the elastic limit of a bar and its working load became almost discredited, and engineers employed the ultimate strength only in deducing the safe working load to which their structures might be subjected. Still, as experience accumulated it was observed that a higher factor of safety was required for a live load than for a dead one.

In 1871 Wöhler published the results of a number of experiments on bars of iron and steel subjected to live loads. In these experiments the stresses were put on and removed from the specimens without impact, but it was, nevertheless, found that the breaking stress of the materials was in every case much below the statical breaking load. Thus, a bar of Krupp's axle steel having a tenacity of 49 tons per square inch broke with a stress of 28.6 tons per square inch, when the load was completely removed and replaced without impact 170,000 times. These experiments were made on a large

number of different brands of iron and steel, and the results were concordant in showing that a bar would break with an alternating stress of only, say, one third the statical breaking strength of the material, if the repetitions of stress were sufficiently numerous. At the same time, however, it appeared from the general trend of the experiments that a bar would stand an indefinite number of alternations of stress, provided the stress was kept below the limit.

Prof. Bauschinger defines the elastic limit as the point at which stress ceases to be sensibly proportional to strain, the latter being measured with a mirror apparatus reading to  $\frac{1}{5000}$ th of a millimetre, or about  $\frac{1}{100000}$  in.

This limit is always below the yield-point, and may on occasion be zero. On loading a bar above the yield-point, this point rises with the stress, and the rise continues for weeks, months, and possibly for years if the bar is left at rest under its load. On the other hand, when a bar is loaded beyond its true elastic limit, but below its yield-point, this limit rises, but reaches a maximum as the yield-point, is approached, and then falls rapidly, reaching even to zero. On leaving the bar at rest under a stress exceeding that of its primitive breaking-down point the elastic limit begins to rise again, and may, if left a sufficient time, rise to a point much exceeding its previous value.

This property of the elastic limit of changing with the history of a bar has done more to discredit it than anything else, nevertheless it now seems as if it, owing to this very property, were once more to take its former place in the estimation of engineers, and this time with fixity of tenure. It had long been known that the limit of elasticity might be raised, as we have said, to almost any point within the breaking load of a bar. Thus, in some experiments by Professor Styffe, the elastic limit of a puddled-steel bar was raised 16,000 lbs. by subjecting the bar to a load exceeding its primitive elastic limit.

A bar has two limits of elasticity, one for tension and one for compression. Bauschinger loaded a number of bars in tension until stress ceased to be sensibly proportional to strain. The load was then removed and the bar tested in compression until the elastic limit in this direction had been exceeded. This process raises the elastic limit in compression, as would be found on testing the bar in compression a second time. In place of this, however, it was now again tested in tension, when it was found that the artificial raising of the limit in compression had lowered that in tension below its previous value. By repeating the process of alternately testing in tension and compression, the two limits took up points at equal distances from the line of no load, both in tension and compression. These limits Bauschinger calls natural elastic limits of the bar, which for wrought iron correspond to a stress of about  $8\frac{1}{2}$  tons per square inch, but this is practically the limiting load to which a bar of the same material can be strained alternately in tension and compression, without breaking when the loading is repeated sufficiently often, as determined by Wöhler's method.

As received from the rolls the elastic limit of the bar in tension is above the natural elastic limit of the bar as defined by Bauschinger, having been artificially raised by the deformations to which it has been subjected in the process of manufacture. Hence, when subjected to alternating stresses, the limit in tension is immediately lowered, while that in compression is raised until they both correspond to equal loads. Hence, in Wöhler's experiments, in which the bars broke at loads nominally below the elastic limits of the material, there is every reason for concluding that the loads were really greater than true elastic limits of the material. This is confirmed by tests on the connecting-rods of engines, which of course work under alternating stresses of equal intensity. Careful experiments on old rods show that the elastic limit in compression is the same as that in tension, and that both are far below the tension elastic limit of the material as received from the rolls.

The common opinion that straining a metal beyond its elastic limit injures it appears to be untrue. It is not the mere straining of a metal beyond one elastic limit that injures it, but the straining, many times repeated, beyond its two elastic limits. Sir Benjamin Baker has shown that in bending a shell plate for a boiler the metal is of necessity strained beyond its elastic limit, so that stresses of as much as 7 tons to 15 tons per square inch may obtain in it as it comes from the rolls, and unless the plate is annealed, these stresses will still exist after it has been built into the boiler. In such a case, however, when exposed to the additional stress due to the pressure inside

the boiler, the overstrained portions of the plate will relieve themselves by stretching and taking a permanent set, so that probably after a year's working very little difference could be detected in the stresses in a plate built into the boiler as it came from the bending rolls, and in one which had been annealed, before riveting into place, and the first, in spite of its having been strained beyond its elastic limits, and not subsequently annealed, would be as strong as the other.

### Resistance of Metals to Repeated Shocks.

More than twelve years were spent by Wöhler at the instance of the Prussian Government in experimenting upon the resistance of iron and steel to repeated stresses. The results of his experiments are expressed in what is known as Wöhler's law, which is given in the following words in Dubois's translation of Weyrauch:

"Rupture may be caused not only by a steady load which exceeds the carrying strength, but also by repeated applications of stresses, none of which are equal to the carrying strength. The differences of these stresses are measures of the disturbance of continuity, in so far as by their increase the minimum stress which is still necessary for rupture diminishes."

A practical illustration of the meaning of the first portion of this law may be given thus: If 50,000 pounds once applied will just break a bar of iron or steel, a stress very much less than 50,000 pounds will break it if repeated sufficiently often.

This is fully confirmed by the experiments of Fairbairn and Spangenberg, as well as those of Wöhler; and, as is remarked by Weyrauch, it may be considered as a long-known result of common experience. It partially accounts for what Mr. Holley has called the "intrinsically ridiculous factor of safety of six."

Another "long-known result of experience" is the fact that rupture may be caused by a succession of *shocks* or *impacts*, none of which alone would be sufficient to cause it. Iron axles, the piston-rods of steam hammers, and other pieces of metal subject to continuously repeated shocks, invariably break after a certain length of service. They have a "life" which is limited.

Several years ago Fairbairn wrote: "We know that in some cases wrought iron subjected to continuous vibration assumes a crystalline structure, and that the cohesive powers are much deteriorated, but we are ignorant of the causes of this change." We are still ignorant, not only of the causes of this change, but of the conditions under which it takes place. Who knows whether wrought iron subjected to very slight continuous vibration will endure forever? or whether to insure final rupture each of the continuous small shocks must amount at least to a certain percentage of single heavy shock (both measured in foot-pounds), which would cause rupture with one application? Wöhler found in testing iron by repeated stresses (not impacts) that in one case 400,000 applications of a stress of 500 centners to the square inch caused rupture, while a similar bar remained sound after 48,000,000 applications of a stress of 300 centners to the square inch (1 centner = 110.2 lbs.).

Who knows whether or not a similar law holds true in regard to repeated shocks? Suppose that a bar of iron would break under a single impact of 1000 foot-pounds, how many times would it be likely to bear the repetition of 100 foot-pounds, or would it be safe to allow it to remain for fifty years subjected to a continual succession of blows of even 10 foot-pounds each?

Mr. William Metcalf published in the *Metallurgical Review*, Dec. 1877, the results of some tests of the life of steel of different percentages of carbon under impact. Some small steel pitmans were made, the specifications for which required that the unloaded machine should run  $4\frac{1}{2}$  hours at the rate of 1200 revolutions per minute before breaking.

The steel was all of uniform quality, except as to carbon. Here are the results; The

- .30 C. ran 1 h. 21 m. Heated and bent before breaking.
- .49 C. " 1 h. 28 m., " " " " " "
- .43 C. " 4 h. 57 m. Broke without heating.
- .65 C. " 3 h. 50 m. Broke at weld where imperfect.
- .80 C. " 5 h. 40 m.
- .84 C. " 18 h.
- .87 C. Broke in weld near the end.
- .96 C. Ran 4.55 m., and the machine broke down.

Some other experiments by Mr. Metcalf confirmed his conclusion, viz.

that high-carbon steel was better adapted to resist repeated shocks and vibrations than low-carbon steel.

These results, however, would scarcely be sufficient to induce any engineer to use .84 carbon steel in a car-axle or a bridge-rod. Further experiments are needed to confirm or overthrow them.

(See description of proposed apparatus for such an investigation in the author's paper in *Trans. A. I. M. E.*, vol. viii., p. 76, from which the above extract is taken.)

**Stresses Produced by Suddenly Applied Forces and Shocks.**

(Mansfield Merriman, *R. R. & Eng. Jour.*, Dec. 1889.)

Let  $P$  be the weight which is dropped from a height  $h$  upon the end of a bar, and let  $y$  be the maximum elongation which is produced. The work performed by the falling weight, then, is

$$W = P(h + y),$$

and this must equal the internal work of the resisting molecular stresses. The stress in the bar, which is at first 0, increases up to a certain limit  $Q$ , which is greater than  $P$ ; and if the elastic limit be not exceeded the elongation increases uniformly with the stress, so that the internal work is equal to the mean stress  $1/2Q$  multiplied by the total elongation  $y$ , or

$$W = 1/2 Qy.$$

Whence, neglecting the work that may be dissipated in heat,

$$1/2 Qy = Ph + Py.$$

If  $e$  be the elongation due to the static load  $P$ , within the elastic limit  $y = \frac{Q}{P} e$ ; whence

$$Q = P \left( 1 + \sqrt{1 + 2 \frac{h}{e}} \right), \dots \dots \dots (1)$$

which gives the momentary maximum stress. Substituting this value of  $Q$ , there results

$$y = e \left( 1 + \sqrt{1 + 2 \frac{h}{e}} \right), \dots \dots \dots (2)$$

which is the value of the momentary maximum elongation.

A shock results when the force  $P$ , before its action on the bar, is moving with velocity, as is the case when a weight  $P$  falls from a height  $h$ . The above formulas show that this height  $h$  may be small if  $e$  is a small quantity, and yet very great stresses and deformations be produced. For instance, let  $h = 4e$ , then  $Q = 4P$  and  $y = 4e$ ; also let  $h = 12e$ , then  $Q = 6P$  and  $y = 6e$ . Or take a wrought-iron bar 1 in. square and 5 ft. long: under a steady load of 5000 lbs. this will be compressed about 0.012 in., supposing that no lateral flexure occurs; but if a weight of 5000 lbs. drops upon its end from the small height of 0.048 in. there will be produced the stress of 20,000 lbs.

A suddenly applied force is one which acts with the uniform intensity  $P$  upon the end of the bar, but which has no velocity before acting upon it. This corresponds to the case of  $h = 0$  in the above formulas, and gives  $Q = 2P$  and  $y = 2e$  for the maximum stress and maximum deformation. Probably the action of a rapidly-moving train upon a bridge produces stresses of this character.

**Increasing the Tensile Strength of Iron Bars by Twisting them.**—Ernest L. Ransome of San Francisco has obtained an English Patent, No. 16221 of 1888, for an "improvement in strengthening and testing wrought metal and steel rods or bars, consisting in twisting the same in a cold state. . . . Any defect in the lamination of the metal which would otherwise be concealed is revealed by twisting, and imperfections are shown at once. The treatment may be applied to bolts, suspension-rods or bars subjected to tensile strength of any description."

Results of tests of this process were reported by Lieutenant F. P. Gilmore, U. S. N., in a paper read before the Technical Society of the Pacific Coast, published in the *Transactions of the Society* for the month of December, 1888. The experiments include trials with thirty-nine bars, twenty-nine of which were variously twisted, from three-eighths of one turn to six turns per foot. The test-pieces were cut from one and the same bar, and accurately

measured and numbered. From each lot two pieces without twist were tested for tensile strength and ductility. One group of each set was twisted until the pieces broke, as a guide for the amount of twist to be given those to be tested for tensile strain.

The following is the result of one set of Lieut. Gilmore's tests, on iron bars 8 in. long, .719 in. diameter.

No. of Bars.	Conditions.	Twists in Turns.	Twists per ft.	Tensile Strength.	Tensile per sq. in.	Gain per cent.
2	Not twisted.	0	0	22,000	54,180	
2	Twisted cold.	$\frac{1}{2}$	$\frac{3}{4}$	23,900	59,020	9
2	" "	1	$1\frac{1}{2}$	25,800	63,500	17
2	" "	2	3	26,300	64,750	19
1	" "	$2\frac{1}{2}$	$3\frac{3}{4}$	26,400	65,000	20

Tests that corroborated these results were made by the University of California in 1889 and by the Low Moor Iron Works, England, in 1890.

### TENSILE STRENGTH.

The following data are usually obtained in testing by tension in a testing-machine a sample of a material of construction:

The load and the amount of extension at the elastic limit.

The maximum load applied before rupture.

The elongation of the piece, measured between gauge-marks placed a stated distance apart before the test; and the reduction of area at the point of fracture.

The load at the elastic limit and the maximum load are recorded in pounds per square inch of the original area. The elongation is recorded as a percentage of the stated length between the gauge-marks, and the reduction area as a percentage of the original area. The coefficient of elasticity is calculated from the ratio the extension within the elastic limit per inch of length bears to the load per square inch producing that extension.

On account of the difficulty of making accurate measurements of the fractured area of a test-piece, and of the fact that elongation is more valuable than reduction of area as a measure of ductility and of resilience or work of resistance before rupture, modern experimenters are abandoning the custom of reporting reduction of area. The "strength per square inch of fractured section" formerly frequently used in reporting tests is now almost entirely abandoned. The data now calculated from the results of a tensile test for commercial purposes are: 1. Tensile strength in pounds per square inch of original area. 2. Elongation per cent of a stated length between gauge-marks, usually 8 inches. 3. Elastic limit in pounds per square inch of original area.

The short or grooved test specimen gives with most metals, especially with wrought iron and steel, an apparent tensile strength much higher than the real strength. This form of test-piece is now almost entirely abandoned.

The following results of the tests of six specimens from the same  $1\frac{1}{4}$ " steel bar illustrate the apparent elevation of elastic limit and the changes in other properties due to change in length of stems which were turned down in each specimen to .798" diameter. (Jas. E. Howard, Eng. Congress 1893 Section G.)

Description of Stem.	Elastic Limit, Lbs. per Sq. In.	Tensile Strength, Lbs. per Sq. In.	Contraction of Area, per cent.
1.00" long.....	64,900	94,400	49.0
.50 " .....	65,320	97,800	43.4
.25 " .....	68,000	102,420	39.6
Semicircular groove, .4" radius.....	75,000	116,380	31.6
Semicircular groove, $\frac{1}{8}$ " radius .....	86,000, about	134,960	23.0
V-shaped groove .....	90,000, about	117,000	Indeterminate.

Tests plate made by the author in 1879 of straight and grooved test-pieces of boiler-plate steel cut from the same gave the following results :

5 straight pieces, 56,605 to 59,012 lbs. T. S. Aver. 57,566 lbs.  
 4 grooved " 64,341 to 67,400 " " " 65,452 "

Excess of the short or grooved specimen, 21 per cent, or 12,114 lbs.

**Measurement of Elongation.**—In order to be able to compare records of elongation, it is necessary not only to have a uniform length of section between gauge-marks (say 8 inches), but to adopt a uniform method of measuring the elongation to compensate for the difference between the apparent elongation when the piece breaks near one of the gauge-marks, and when it breaks midway between them. The following method is recommended (Trans. A. S. M. E., vol. xi., p. 622):

Mark on the specimen divisions of 1/2 inch each. After fracture measure from the point of fracture the length of 8 of the marked spaces on each fractured portion (or 7 + on one side and 8 + on the other if the fracture is not at one of the marks). The sum of these measurements, less 8 inches, is the elongation of 8 inches of the original length. If the fracture is so near one end of the specimen that 7 + spaces are not left on the shorter portion, then take the measurement of as many spaces (with the fractional part next to the fracture) as are left, and for the spaces lacking add the measurement of as many corresponding spaces of the longer portion as are necessary to make the 7 + spaces.

**Shapes of Specimens for Tensile Tests.**—The shapes shown in Fig. 75 were recommended by the author in 1882 when he was connected

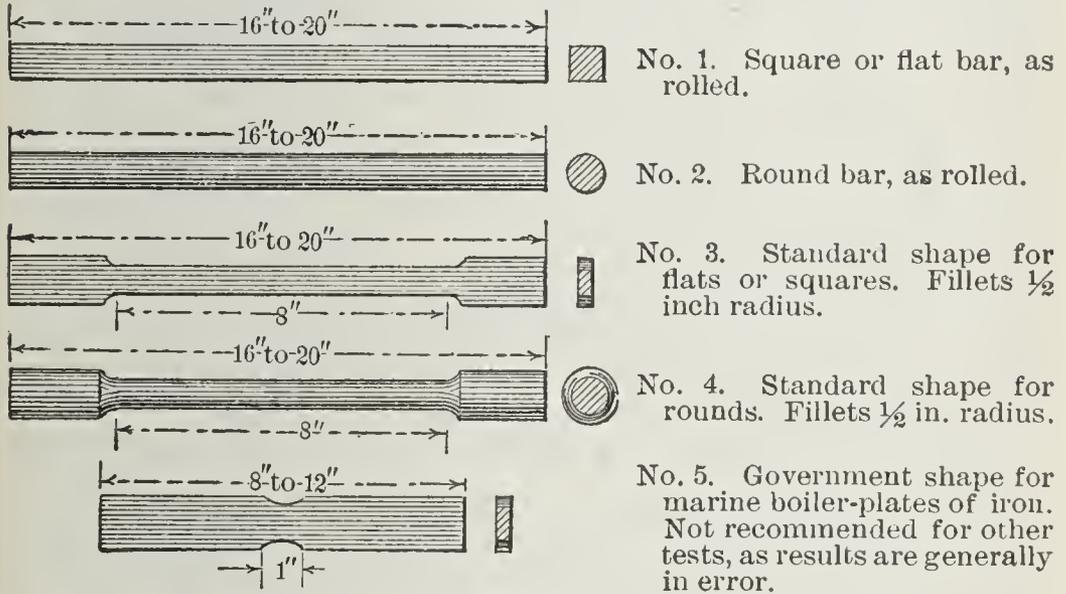

FIG. 75.

with the Pittsburgh Testing Laboratory. They are now in most general use, the earlier forms, with 5 inches or less in length between shoulders, being almost entirely abandoned.

**Precautions Required in making Tensile Tests.**—The testing-machine itself should be tested, to determine whether its weighing apparatus is accurate, and whether it is so made and adjusted that in the test of a properly made specimen the line of strain of the testing-machine is absolutely in line with the axis of the specimen.

The specimen should be so shaped that it will not give an incorrect record of strength.

It should be of uniform minimum section for not less than five inches of its length.

Regard must be had to the time occupied in making tests of certain materials. Wrought iron and soft steel can be made to show a higher than their actual apparent strength by keeping them under strain for a great length of time.

In testing soft alloys, copper, tin, zinc, and the like, which flow under constant strain their highest apparent strength is obtained by testing them rapidly. In recording tests of such materials the length of time occupied in the test should be stated.

For very accurate measurements of elongation, corresponding to increments of load during the tests, the electric contact micrometer, described in *Trans. A. S. M. E.*, vol. vi., p. 479, will be found convenient. When readings of elongation are then taken during the test, a strain diagram may be plotted from the reading, which is useful in comparing the qualities of different specimens. Such strain diagrams are made automatically by the new Olsen testing-machine, described in *Jour. Frank. Inst.* 1891.

The coefficient of elasticity should be deduced from measurement observed between fixed increments of load per unit section, say between 2000 and 12,000 pounds per square inch or between 1000 and 11,000 pounds instead of between 0 and 10,000 pounds.

### COMPRESSIVE STRENGTH.

What is meant by the term "compressive strength" has not yet been settled by the authorities, and there exists more confusion in regard to this term than in regard to any other used by writers on strength of materials. The reason of this may be easily explained. The effect of a compressive stress upon a material varies with the nature of the material, and with the shape and size of the specimen tested. While the effect of a tensile stress is to produce rupture or separation of particles in the direction of the line of strain, the effect of a compressive stress on a piece of material may be either to cause it to fly into splinters, to separate into two or more wedge-shaped pieces and fly apart, to bulge, buckle, or bend, or to flatten out and utterly resist rupture or separation of particles. A piece of speculum metal under compressive stress will exhibit no change of appearance until rupture takes place, and then it will fly to pieces as suddenly as if blown apart by gunpowder. A piece of cast iron or of stone will generally split into wedge-shaped fragments. A piece of wrought iron will buckle or bend. A piece of wood or zinc may bulge, but its action will depend upon its shape and size. A piece of lead will flatten out and resist compression till the last degree; that is, the more it is compressed the greater becomes its resistance.

Air and other gaseous bodies are compressible to any extent as long as they retain the gaseous condition. Water not confined in a vessel is compressed by its own weight to the thickness of a mere film, while when confined in a vessel it is almost incompressible.

It is probable, although it has not been determined experimentally, that solid bodies when confined are at least as incompressible as water. When they are not confined, the effect of a compressive stress is not only to shorten them, but also to increase their lateral dimensions or bulge them. Lateral strains are therefore induced by compressive stresses.

The weight per square inch of original section required to produce any given amount or percentage of shortening of any material is not a constant quantity, but varies with both the length and the sectional area, with the shape of this sectional area, and with the relation of the area to the length. The "compressive strength" of a material, if this term be supposed to mean the weight in pounds per square inch necessary to cause rupture, may vary with every size and shape of specimen experimented upon. Still more difficult would it be to state what is the "compressive strength" of a material which does not rupture at all, but flattens out. Suppose we are testing a cylinder of a soft metal like lead, two inches in length and one inch in diameter, a certain weight will shorten it one per cent, another weight ten per cent, another fifty per cent, but no weight that we can place upon it will rupture it, for it will flatten out to a thin sheet. What, then, is its compressive strength? Again, a similar cylinder of soft wrought iron would probably compress a few per cent, bulging evenly all around; it would then commence to bend, but at first the bend would be imperceptible to the eye and too small to be measured. Soon this bend would be great enough to be noticed, and finally the piece might be bent nearly double, or otherwise distorted. What is the "compressive strength" of this piece of iron? Is it the weight per square inch which compresses the piece one per cent or five per cent, that which causes the first bending (impossible to be discovered), or that which causes a perceptible bend?

As showing the confusion concerning the definitions of compressive strength, the following statements from different authorities on the strength of wrought iron are of interest.

Wood's Resistance of Materials states, "comparatively few experiments have been made to determine how much wrought iron will sustain at the point of crushing. Hodgkinson gives 65,000, Rondulet 70,800, Weisbach 72,000

Rankine 30,000 to 40,000. It is generally assumed that wrought iron will resist about two thirds as much crushing as to tension, but the experiments fail to give a very definite ratio."

Mr. Whipple, in his treatise on bridge-building, states that a bar of good wrought iron will sustain a tensile strain of about 60,000 pounds per square inch, and a compressive strain, in pieces of a length not exceeding twice the least diameter, of about 90,000 pounds.

The following values, said to be deduced from the experiments of Major Wade, Hodgkinson, and Capt. Meigs, are given by Haswell :

American wrought iron.....	127,720 lbs.
"    "    " (mean).....	85,500 "
English    "    " .....	65,200 "
	40,000 "

Stoney states that the strength of short pillars of any given material, all having the same diameter, does not vary much, provided the length of the piece is not less than one and does not exceed four or five diameters, and that the weight which will just crush a short prism whose base equals one square inch, and whose height is not less than 1 to 1½ and does not exceed 4 or 5 diameters, is called the crushing strength of the material. It would be well if experimenters would all agree upon some such definition of the term "crushing strength," and insist that all experiments which are made for the purpose of testing the relative values of different materials in compression be made on specimens of exactly the same shape and size. An arbitrary size and shape should be assumed and agreed upon for this purpose. The size mentioned by Stoney is definite as regards area of section, viz., one square inch, but is indefinite as regards length, viz., from one to five diameters. In some metals a specimen five diameters long would bend, and give a much lower apparent strength than a specimen having a length of one diameter. The words "will just crush" are also indefinite for ductile materials, in which the resistance increases without limit if the piece tested does not bend. In such cases the weight which causes a certain percentage of compression, as five, ten, or fifty per cent, should be assumed as the crushing strength.

For future experiments on crushing strength three things are desirable : First, an arbitrary standard shape and size of test specimen for comparison of all materials. Secondly, a standard limit of compression for ductile materials, which shall be considered equivalent to fracture in brittle materials. Thirdly, an accurate knowledge of the relation of the crushing strength of a specimen of standard shape and size to the crushing strength of specimens of all other shapes and sizes. The latter can only be secured by a very extensive and accurate series of experiments upon all kinds of materials, and on specimens of a great number of different shapes and sizes.

The author proposes, as a standard shape and size, for a compressive test specimen for all metals, a cylinder one inch in length, and one half square inch in sectional area, or 0.798 inch diameter; and for the limit of compression equivalent to fracture, ten per cent of the original length. The term "compressive strength," or "compressive strength of standard specimen," would then mean the weight per square inch required to fracture by compressive stress a cylinder one inch long and 0.798 inch diameter, or to reduce its length to 0.9 inch if fracture does not take place before that reduction in length is reached. If such a standard, or any standard size whatever, had been used by the earlier authorities on the strength of materials, we never would have had such discrepancies in their statements in regard to the compressive strength of wrought iron as those given above.

The reasons why this particular size is recommended are : that the sectional area, one-half square inch, is as large as can be taken in the ordinary testing-machines of 100,000 pounds capacity, to include all the ordinary metals of construction, cast and wrought iron, and the softer steels; and that the length, one inch, is convenient for calculation of percentage of compression. If the length were made two inches, many materials would bend in testing, and give incorrect results. Even in cast iron Hodgkinson found as the mean of several experiments on various grades, tested in specimens ¾ inch in height, a compressive strength per square inch of 94,730 pounds, while the mean of the same number of specimens of the same irons tested in pieces 1½ inches in height was only 88,800 pounds. The best size and shape of standard specimen should, however, be settled upon only after consultation and agreement among several authorities.

The Committee on Standard Tests of the American Society of Mechanical Engineers say (vol. xi., p. 624):

“Although compression tests have heretofore been made on diminutive sample pieces, it is highly desirable that tests be also made on long pieces from 10 to 20 diameters in length, corresponding more nearly with actual practice, in order that elastic strain and change of shape may be determined by using proper measuring apparatus.

The elastic limit, modulus or coefficient of elasticity, maximum and ultimate resistances, should be determined, as well as the increase of section at various points, viz., at bearing surfaces and at crippling point.

The use of long compression-test pieces is recommended, because the investigation of short cubes or cylinders has led to no direct application of the constants obtained by their use in computation of actual structures, which have always been and are now designed according to empirical formulæ obtained from a few tests of long columns.”

**COLUMNS, PILLARS, OR STRUTS.**

**Hodgkinson's Formula for Columns.**

$P$  = crushing weight in pounds;  $d$  = exterior diameter in inches;  $d_1$  = interior diameter in inches;  $L$  = length in feet.

Kind of Column.	Both ends rounded, the length of the column exceeding 15 times its diameter.	Both ends flat, the length of the column exceeding 30 times its diameter.
Solid cylindrical columns of cast iron.....	$P = 33,380 \frac{d^{3.76}}{L^{1.7}}$	$P = 98,920 \frac{d^{3.55}}{L^{1.7}}$
Hollow cylindrical columns of cast iron.....	$P = 29,120 \frac{d^{3.76} - d_1^{3.76}}{L^{1.7}}$	$P = 99,320 \frac{d^{3.55} - d_1^{3.55}}{L^{1.7}}$
Solid cylindrical columns of wrought iron.	$P = 95,850 \frac{d^{3.76}}{L^2}$	$P = 299,600 \frac{d^{3.55}}{L^2}$
Solid square pillar of Dantzic oak (dry)....	.....	$P = 24,540 \frac{d^4}{L^2}$
Solid square pillar of red deal (dry).....	.....	$P = 17,510 \frac{d^4}{L^2}$

The above formulæ apply only in cases in which the length is so great that the column breaks by bending and not by simple crushing. If the column be shorter than that given in the table, and more than four or five times its diameter, the strength is found by the following formula :

$$W = \frac{PCK}{P + \frac{3}{4}CK}$$

in which  $P$  = the value given by the preceding formulæ,  $K$  = the transverse section of the column in square inches,  $C$  = the ultimate compressive resistance of the material, and  $W$  = the crushing strength of the column.

Hodgkinson's experiments were made upon comparatively short columns, the greatest length of cast-iron columns being  $60\frac{1}{2}$  inches, of wrought iron  $90\frac{3}{4}$  inches.

The following are some of his conclusions:

1. In all long pillars of the same dimensions, when the force is applied in the direction of the axis, the strength of one which has flat ends is about three times as great as one with rounded ends.
2. The strength of a pillar with one end rounded and the other flat is an arithmetical mean between the two given in the preceding case of the same dimensions.
3. The strength of a pillar having both ends firmly fixed is the same as one of half the length with both ends rounded.
4. The strength of a pillar is not increased more than one seventh by enlarging it at the middle.

**Gordon's formulæ** deduced from Hodgkinson's experiments are more generally used than Hodgkinson's own. They are:

Columns with both ends fixed or flat,  $P = \frac{fS}{1 + a\frac{l^2}{r^2}}$ ;

Columns with one end flat, the other end round,  $P = \frac{fS}{1 + 1.8a\frac{l^2}{r^2}}$ ;

Columns with both ends round, or hinged,  $P = \frac{fS}{1 + 4a\frac{l^2}{r^2}}$ ;

$S$  = area of cross-section in inches;

$P$  = ultimate resistance of column, in pounds;

$f$  = crushing strength of the material in lbs. per square inch;

$r$  = least radius of gyration, in inches,  $r^2 = \frac{\text{Moment of inertia}}{\text{area of section}}$ ;

$l$  = length of column in inches;

$a$  = a coefficient depending upon the material;

$f$  and  $a$  are usually taken as constants; they are really empirical variables, dependent upon the dimensions and character of the column as well as upon the material. (Burr.)

For solid wrought-iron columns, values commonly taken are:  $f = 36,000$  to  $40,000$ ;  $a = 1/36,000$  to  $1/40,000$ .

For solid cast-iron columns,  $f = 80,000$ ,  $a = 1/6400$ .

For hollow cast-iron columns, fixed ends,  $p = \frac{80,000}{1 + \frac{1}{800}\frac{l^2}{d^2}}$ ,  $l$  = length and

$d$  = diameter in the same unit, and  $p$  = strength in lbs. per square inch.

The coefficient of  $l^2/d^2$  is given various values, as  $1/400$ ,  $1/500$ ,  $1/600$ , and  $1/800$ , by different writers. The use of Gordon's formula, with any coefficients derived from Hodgkinson's experiments, for cast-iron columns is to be deprecated. See Strength of Cast-iron Columns, pp. 250, 251.

Sir Benjamin Baker gives,

For mild steel,  $f = 67,000$  lbs.,  $a = 1/22,400$ .

For strong steel,  $f = 114,000$  lbs.,  $a = 1/14,400$

Prof. Burr considers these only loose approximations for the ultimate resistances. See his formulæ on p. 259.

For dry timber Rankine gives  $f = 7200$  lbs.,  $a = 1/3000$ .

### MOMENT OF INERTIA AND RADIUS OF GYRATION.

**The moment of inertia** of a section is the sum of the products of each elementary area of the section into the square of its distance from an assumed axis of rotation, as the neutral axis.

**The radius of gyration** of the section equals the square root of the quotient of the moment of inertia divided by the area of the section. If  $R$  = radius of gyration,  $I$  = moment of inertia and  $A$  = area,

$$R = \sqrt{\frac{I}{A}}. \quad \frac{I}{A} = R^2.$$

The moments of inertia of various sections are as follows:

$d$  = diameter, or outside diameter;  $d_1$  = inside diameter;  $b$  = breadth;

$h$  = depth;  $b_1$ ,  $h_1$ , inside breadth and diameter;

Solid rectangle  $I = 1/12bh^3$ ; Hollow rectangle  $I = 1/12(bh^3 - b_1h_1^3)$ ;

Solid square  $I = 1/12b^4$ ; Hollow square  $I = 1/12(b^4 - b_1^4)$ ;

Solid cylinder  $I = 1/64\pi d^4$ ; Hollow cylinder  $I = 1/64\pi(d^4 - d_1^4)$ .

**Moments of Inertia and Radius of Gyration for Various Sections, and their Use in the Formulas for Strength of Girders and Columns.**—The strength of sections to resist strains,

either as girders or as columns, depends not only on the area but also on the form of the section, and the property of the section which forms the basis of the constants used in the formulas for strength of girders and columns to express the effect of the form, is its moment of inertia about its neutral axis. The modulus of resistance of any section to transverse bending is its

moment of inertia divided by the distance from the neutral axis to the fibres farthest removed from that axis; or

$$\text{Section modulus} = \frac{\text{Moment of inertia}}{\text{Distance of extreme fibre from axis}} \quad Z = \frac{I}{y}$$

**Moment of resistance** = section modulus  $\times$  unit stress on extreme fibre.

**Moment of Inertia of Compound Shapes.** (Pencoyd Iron Works.)—The moment of inertia of any section about any axis is equal to the  $I$  about a parallel axis passing through its centre of gravity  $+$  (the area of the section  $\times$  the square of the distance between the axes).

By this rule, the moments of inertia or radii of gyration of any single sections being known, corresponding values may be obtained for any combination of these sections.

**Radius of Gyration of Compound Shapes.**—In the case of a pair of any shape without a web the value of  $R$  can always be found without considering the moment of inertia.

The radius of gyration for any section around an axis parallel to another axis passing through its centre of gravity is found as follows:

Let  $r$  = radius of gyration around axis through centre of gravity;  $R$  = radius of gyration around another axis parallel to above;  $d$  = distance between axes:  $R = \sqrt{d^2 + r^2}$ .

When  $r$  is small,  $R$  may be taken as equal to  $d$  without material error.

**Graphical Method for Finding Radius of Gyration.**—Benj. F. La Rue, *Eng. News*, Feb. 2, 1893, gives a short graphical method for finding the radius of gyration of hollow, cylindrical, and rectangular columns, as follows:

For cylindrical columns:

Lay off to a scale of 4 (or 40) a right-angled triangle, in which the base equals the outer diameter, and the altitude equals the inner diameter of the column, or *vice versa*. The hypotenuse, measured to a scale of unity (or 10), will be the radius of gyration sought.

This depends upon the formula

$$G = \sqrt{\frac{\text{Mom. of Inertia}}{\text{Area}}} = \frac{\sqrt{D^2 + d^2}}{4}$$

in which  $A$  = area and  $D$  = diameter of outer circle,  $a$  = area and  $d$  = diameter of inner circle, and  $G$  = radius of gyration.  $\sqrt{D^2 + d^2}$  is the expression for the hypotenuse of a right-angled triangle, in which  $D$  and  $d$  are the base and altitude.

The sectional area of a hollow round column is  $.7854(D^2 - d^2)$ . By constructing a right-angled triangle in which  $D$  equals the hypotenuse and  $d$  equals the altitude, the base will equal  $\sqrt{D^2 - d^2}$ . Calling the value of this expression for the base  $B$ , the area will equal  $.7854B^2$ .

Value of  $G$  for square columns:

Lay off as before, but using a scale of 10, a right-angled triangle of which the base equals  $D$  or the side of the outer square, and the altitude equals  $d$ , the side of the inner square. With a scale of 3 measure the hypotenuse, which will be, approximately, the radius of gyration.

This process for square columns gives an excess of slightly more than 4%. By deducting 4% from the result, a close approximation will be obtained.

A very close result is also obtained by measuring the hypotenuse with the same scale by which the base and altitude were laid off, and multiplying by the decimal 0.29; more exactly, the decimal is 0.28867.

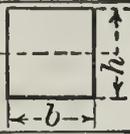

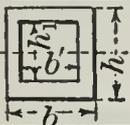

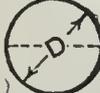

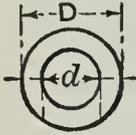

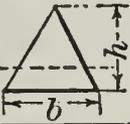

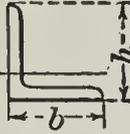

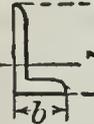

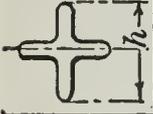

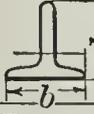

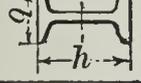

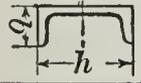

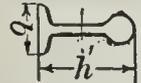

The formula is

$$G = \sqrt{\frac{\text{Mom. of inertia}}{\text{Area}}} = \frac{1}{\sqrt{12}} \sqrt{D^2 + d^2} = 0.28867 \sqrt{D^2 + d^2}$$

This may also be applied to any rectangular column by using the lesser diameters of an unsupported column, and the greater diameters if the column is supported in the direction of its least dimensions.

### ELEMENTS OF USUAL SECTIONS.

Moments refer to horizontal axis through centre of gravity. This table is intended for convenient application where extreme accuracy is not important. Some of the terms are only approximate; those marked \* are correct. Values for radius of gyration in flanged beams apply to standard minimum sections only.  $A$  = area of section;  $b$  = breadth;  $h$  = depth;  $D$  = diameter.

Shape of Section.	Moment of Inertia.	Section Modulus.	Square of Least Radius of Gyration.	Least Radius of Gyration.
 Solid Rect-angle.	$\frac{bh^3}{12} *$	$\frac{bh^2}{6} *$	$\frac{(\text{Least side})^2}{12} *$	$\frac{\text{Least side}}{3.46} *$
 Hollow Rect-angle.	$\frac{bh^3 - b_1h_1^3}{12} *$	$\frac{bh^3 - b_1h_1^3}{6h} *$	$\frac{h^2 + h_1^2}{12} *$	$\frac{h + h_1}{4.89}$
 Solid Circle.	$\frac{AD^2}{16} *$	$\frac{AD}{8} *$	$\frac{D^2}{16} *$	$\frac{D}{4} *$
 Hollow Circle. A, area of large section; a, area of small section.	$\frac{AD^2 - ad^2}{16}$	$\frac{AD^2 - ad^2}{8D}$	$\frac{D^2 + d^2}{16} *$	$\frac{D + d}{5.64}$
 Solid Triangle.	$\frac{bh^3}{36}$	$\frac{bh^2}{24}$	The least of of the two: $\frac{h^2}{18}$ or $\frac{b^2}{24}$	The least of the two: $\frac{h}{4.24}$ or $\frac{b}{4.9}$

### The Strength of Cast-iron Columns.

Hodgkinson's experiments (first published in Phil. Trans. Royal Socy., 1840, and condensed in Tredgold on Cast Iron, 4th ed., 1846), and Gordon's formula, based upon them, are still used (1898) in designing cast-iron columns. That they are entirely inadequate as a basis of a practical formula suitable to the present methods of casting columns will be evident from what follows.

Hodgkinson's experiments were made on nine "long" pillars, about  $7\frac{1}{2}$  ft. long, whose external diameters ranged from 1.74 to 2.23 in., and average thickness from 0.29 to 0.35 in., the thickness of each column also varying, and on 13 "short" pillars, 0.733 ft. to 2.251 ft. long, with external diameters from 1.08 to 1.26 in., all of them less than  $\frac{1}{4}$  in. thick. The iron used was Low Moor, Yorkshire, No. 3, said to be a good iron, not very hard, earlier experiments on which had given a tensile strength of 14,535 and a crushing strength of 109,801 lbs. per sq. in. The results of the experiments on the "long" pillars were reduced to the equivalent breaking weight of a solid pillar 1 in. diameter and of the same length,  $7\frac{1}{2}$  ft., which ranged from 2969 to 3587 lbs. per sq. in., a range of over 12 per cent, although the pillars were made from the same iron and of nearly uniform dimensions. From the 13 experiments on "short" pillars a formula was derived, and from it were obtained the "calculated" breaking weights, the actual breaking weights ranging from about 8 per cent above to about 8 per cent below the calculated weights, a total range of about 16 per cent. Modern cast-iron columns, such as are used in the construction of buildings, are very different in size, proportions, and quality of iron from the slender "long" pillars used in Hodgkinson's experiments. There is usually no check, by actual tests or by disinterested inspection, upon the quality of the material. The tensile, compressive, and transverse strength of cast iron varies through a great range (the tensile strength ranging from less than 10,000 to over 40,000 lbs. per sq. in.), with variations in the chemical composition of the iron, according to laws which are as yet very imperfectly understood, and with variations in the method of melting and of casting. There is also a wide variation in the strength of iron of the same melt when cast into bars of different thicknesses. It is therefore impossible to predict even approximately, from the data given by Hodgkinson of the strength of columns of Low Moor iron in pillars  $7\frac{1}{2}$  ft. long, 2 in. diam., and  $\frac{1}{8}$  in. thick, what will be the strength of a column made of American cast iron, of a quality not stated, in a column 16 ft. long, 12 or 15 in. diam., and from  $\frac{3}{4}$  in. to  $1\frac{1}{2}$  in. thick.

Another difficulty in obtaining a practical formula for the strength of cast-iron columns is due to the uncertainty of the quality of the casting, and the danger of hidden defects, such as internal stresses due to unequal cooling, cinder or dirt, blow-holes, "cold-shuts," and cracks on the inner surface, which cannot be discovered by external inspection. Variation in thickness, due to rising of the core during casting, is also a common defect.

In addition to the above theoretical or *a priori* objections to the use of Gordon's formula, based on Hodgkinson's experiments, for cast-iron columns, we have the data of recent experiments on full-sized columns, made by the Building Department of New York City (*Eng'g News*, Jan. 13 and 20, 1898). Ten columns in all were tested, six 15-inch, 190 $\frac{1}{2}$  inches long, two 8-inch, 160 inches long, and two 6-inch, 120 inches long. The tests were made on the large hydraulic machine of the Phoenix Bridge Co., of 2,000,000 pounds capacity, which was calibrated for frictional error by the repeated testing within the elastic limit of a large Phoenix column, and the comparison of these tests with others made on the government machine at the Watertown Arsenal. The average frictional error was calculated to be 15.4 per cent, but *Engineering News*, revising the data, makes it 17.1 per cent, with a variation of 3 per cent either way from the average with different loads. The results of the tests of the volumes are given on the opposite page.

Column No. 6 was not broken at the highest load of the testing machine.

Columns Nos. 3 and 4 were taken from the Ireland Building, which collapsed on August 8, 1895; the other four 15-inch columns were made from drawings prepared by the Building Department, as nearly as possible duplicates of Nos. 3 and 4. Nos. 1 and 2 were made by a foundry in New York with no knowledge of their ultimate use. Nos. 5 and 6 were made by a foundry in Brooklyn with the knowledge that they were to be tested. Nos. 7 to 10 were made from drawings furnished by the Department.

TESTS OF CAST-IRON COLUMNS.

Number.	Diam. Inches.	Thickness.			Breaking Load.	
		Max.	Min.	Average.	Pounds.	Pounds per sq. in.
1	15	1	1	1	1,356,000	30,830
2	15	1 5/16	1	1 1/8	1,330,000	27,700
3	15	1 1/4	1	1 1/8	1,198,000	24,900
4	15 1/8	1 7/32	1	1 1/8	1,246,000	25,200
5	15	1 11/16	1	1 11/64	1,632,000	32,100
6	15	1 1/4	1 1/8	1 3/16	2,082,000 +	40,400 +
7	7 3/4 to 8 1/4	1 1/4	5/8	1	651,000	31,900
8	8	1 3/32	1	1 3/64	612,800	26,800
9	6 1/16	1 5/32	1 1/8	1 9/64	400,000	22,700
10	6 3/32	1 1/8	1 1/16	1 7/64	455,200	26,300

Applying Gordon's formula, as used by the Building Department,  $S = \frac{80000a}{1 + \frac{1}{400} \frac{l^2}{d^2}}$ , to these columns gives for the breaking strength per square

inch of the 15-inch columns 57,143 pounds, for the 8-inch columns 40,000 pounds, and for the 6-inch columns 40,000. The strength of columns Nos. 3 and 4 as calculated is 128 per cent more than their actual strength; their actual strength is less than 44 per cent of their calculated strength; and the factor of safety, supposed to be 5 in the Building Law, is only 2.2 for central loading, no account being taken of the likelihood of eccentric loading.

Prof. Lanza, in his *Applied Mechanics*, p. 372, quotes the records of 14 tests of cast-iron mill columns, made on the Watertown testing-machine in 1887-88, the breaking strength per square inch ranging from 25,100 to 63,310 pounds, and showing no relation between the breaking strength per square inch and the dimensions of the columns. Only 3 of the 14 columns had a strength exceeding 33,500 pounds per square inch. The average strength of the other 11 was 29,600 pounds per square inch. Prof. Lanza says that it is evident that in the case of such columns we cannot rely upon a crushing strength of greater than 25,000 or 30,000 pounds per square inch of area of section.

He recommends a factor of safety of 5 or 6 with these figures for crushing strength, or 5000 pounds per square inch of area of section as the highest allowable safe load, and in addition makes the conditions that the length of the column shall not be greatly in excess of 20 times the diameter, that the thickness of the metal shall be such as to insure a good strong casting, and that the sectional area should be increased if necessary to insure that the extreme fibre stress due to probable eccentric loading shall not be greater than 5000 pounds per square inch.

Prof. W. H. Burr (*Eng'g News*, June 30, 1898) gives a formula derived from plotting the results of the Watertown and Phoenixville tests, above described, which represents the average strength of the columns in pounds per square inch. It is  $p = 30,500 - 160l/d$ . It is to be noted that this is an average value, and that the actual strength of many of the columns was much lower. Prof. Burr says: "If cast-iron columns are designed with anything like a reasonable and real margin of safety, the amount of metal required dissipates any supposed economy over columns of mild steel."

**Transverse Strength of Cast-iron Water-pipe.** (*Technology Quarterly*, Sept. 1897.)—Tests of 31 cast-iron pipes by transverse stress gave a maximum outside fibre stress, calculated from maximum load, assuming each half of pipe as a beam fixed at the ends, ranging from 12,800 lbs. to 26,300 lbs. per sq. in.

Bars 2 in. wide cut from the pipes gave moduli of rupture ranging from 28,400 to 51,400 lbs. per sq. in. Four of the tests, bars and pipes:

Moduli of rupture of bar.....	28,400	34,400	40,000	51,400
Fibre stress of pipe... ..	18,300	12,800	14,500	26,300

These figures show a great variation in the strength of both bars and pipes, and also that the strength of the bar does not bear any definite relation to the strength of the pipe.

**Safe Load, in Tons of 2000 Lbs., for Round Cast-iron Columns, with Turned Capitals and Bases.**

Loads being not eccentric, and length of column not exceeding 20 times the diameter. Based on ultimate crushing strength of 25,000 lbs. per sq. in. and a factor of safety of 5. (For eccentric loads see page 254.)

Thick-ness, inches.	Diameter, inches.											
	6	7	8	9	10	11	12	13	14	15	16	18
5/8	26.4	31.3										
3/4	30.9	36.8	42.7	48.6	54.5							
7/8	35.2	42.1	48.9	55.8	62.7	69.6	76.5					
1	39.2	47.1	55.0	62.8	70.7	78.5	86.4	94.2	102.1	110.0		
1 1/8	....	....	60.8	69.6	78.4	87.2	96.1	104.9	113.8	122.6	131.4	
1 1/4	....	....	....	76.1	85.9	95.7	105.5	115.3	125.2	135.0	144.8	164.4
1 3/8	....	....	....	....	93.1	103.9	114.7	125.5	136.3	147.1	157.9	179.5
1 1/2	....	....	....	....	....	....	123.7	135.5	147.3	159.0	170.8	194.4
1 3/4	....	....	....	....	....	....	....	....	168.4	182.1	195.8	223.3
2	....	....	....	....	....	....	....	....	....	204.2	219.9	251.3

For lengths greater than 20 diameters the allowable loads should be decreased. How much they should be decreased is uncertain, since sufficient data of experiments on full-sized very long columns, from which a formula for the strength of such columns might be derived, are as yet lacking. There is, however, rarely, if ever, any need of proportioning cast-iron columns with a length exceeding 20 diameters.

**Safe Loads in Tons of 2000 Pounds for Cast-iron Columns.**

(By the Building Laws of New York City, Boston, and Chicago, 1897.)

	New York.	Boston.	Chicago.
Square columns.....	$\frac{8a}{1 + \frac{l^2}{500d^2}}$	$\frac{5a}{1 + \frac{l^2}{1067d^2}}$	$\frac{5a}{1 + \frac{l^2}{800d^2}}$
Round columns. ....	$\frac{8a}{1 + \frac{l^2}{400d^2}}$	$\frac{5a}{1 + \frac{l^2}{800d^2}}$	$\frac{5a}{1 + \frac{l^2}{600d^2}}$

$a$  = sectional area in square inches;  $l$  = unsupported length of column in inches;  $d$  = side of square column or thickness of round column in inches.

The safe load of a 15-inch round column 1 1/2 inches diameter, 16 feet long according to the laws of these cities would be, in New York, 361 tons; in Boston, 264 tons; in Chicago, 250 tons.

The allowable stress per square inch of area of such a column would be, in New York, 11,350 pounds; in Boston, 8300 pounds; in Chicago, 7850 pounds. A safe stress of 5000 pounds per square inch would give for the safe load on the column 159 tons.

**Strength of Brackets on Cast-iron Columns.**—The columns tested by the New York Building Department referred to above had brackets cast upon them, each bracket consisting of a rectangular shelf supported by one or two triangular ribs. These were tested after the columns had been broken in the principal tests. In 17 out of 22 cases the brackets broke by tearing a hole in the body of the column, instead of by shearing or transverse breaking of the bracket itself. The results were surprisingly low and very irregular. Reducing them to strength per square inch of the total vertical section through the shelf and rib or ribs, they ranged from 2450 to 5600 lbs., averaging 4200 lbs., for a load concentrated at the end of the shelf, and 4100 to 10,900 lbs., averaging 8000 lbs., for a distributed load. (*Eng'g News*, Jan. 20, 1898.)

## Safe Loads, in Tons, for Round Cast Columns.

(In accordance with the Building Laws of Chicago.\*)

Formula:  $w = \frac{5a}{1 + \frac{l^2}{600d^2}}$ .

$w$  = safe load in tons of 2000 pounds;  
 $a$  = cross-section of column;  
 $l$  = unsupported length in inches;  
 $d$  = diameter in inches.

### ECCENTRIC LOADING OF COLUMNS.

In a given rectangular cross-section, such as a masonry joint under pressure, the stress will be distributed uniformly over the section only when the resultant passes through the centre of the section; any deviation from such a central position will bring a maximum unit pressure to one edge and a minimum to the other; when the distance of the resultant from one edge is one third of the entire width of the joint, the pressure at the nearer edge is twice the mean pressure, while that at the farther edge is zero, and that when the resultant approaches still nearer to the edge the pressure at the farther edge becomes less than zero; in fact, becomes a tension, if the material (mortar, etc., there is capable of resisting tension. Or, if, as usual in masonry joints, the material is practically incapable of resisting tension, the pressure at the nearer edge, when the resultant approaches it nearer than one third of the width, increases very rapidly and dangerously, becoming theoretically infinite when the resultant reaches the edge.

With a given position of the resultant relatively to one edge of the joint or section, a similar redistribution of the pressures throughout the section may be brought about by simply adding to, or diminishing the width of the section.

Let  $P$  = the total pressure on any section of a bar of uniform thickness.

$w$  = the width of that section = area of the section, when thickness = 1.

$p$  =  $P/w$  = the mean unit pressure on the section.

$M$  = the maximum unit pressure on the section.

$m$  = the minimum unit pressure on the section.

$d$  = the eccentricity of the resultant = its distance from the centre of the section.

$$\text{Then } M = p \left( 1 + \frac{6d}{w} \right) \text{ and } m = p \left( 1 - \frac{6d}{w} \right).$$

$$\text{When } d = \frac{1}{6}w \text{ then } M = 2p \text{ and } m = 0.$$

When  $d$  is greater than  $1/6w$ , the resultant in that case being less than one third of the width from one edge,  $p$  becomes negative. (J. C. Trautwine, Jr., *Engineering News*, Nov. 23, 1893.)

**Eccentric Loading of Cast-iron Columns.** — Prof. Lanza writes the author as follows: The table on page 252 applies when the resultant of the loads upon the column acts along its central axis, *i.e.*, passes through the centre of gravity of every section. In buildings and other constructions, however, cases frequently occur when the resultant load does not pass through the centre of gravity of the section; and then the pressure is not evenly distributed over the section, but is greatest on the side where the resultant acts. (Examples occur when the loads on the floors are not uniformly distributed.) In these cases the outside fibre stresses of the column should be computed as follows, *viz.*:

Let  $P$  = total pressure on the section;

$d$  = eccentricity of resultant = its distance from the centre of gravity of the section;

$A$  = area of the section, and  $I$  its moment of inertia about an axis in its plane, passing through its centre of gravity, and perpendicular to  $d$  (see page 267);

$c_1$  = distance of most compressed and  $c_2$  = that of least compressed fibre from above stated axis;

$s_1$  = maximum and  $s_2$  = minimum pressure per unit of area. Then

$$s_1 = \frac{P}{A} + \frac{(Pd)c_1}{I} \quad \text{and} \quad s_2 = \frac{P}{A} - \frac{(Pd)c_2}{I}.$$

Having assumed a certain *trial* section for the column to be designed,  $s_1$  should be computed, and, if it exceed the proper safe value, a different section should be used for which  $s_1$  does not exceed this value.

The proper safe value, in the case of cast-iron columns whose ratio of length to diameter does not greatly exceed 20, is 5000 pounds per square inch when the eccentricity used in the computation of  $s_1$  is liable to occur frequently in the ordinary uses of the structure; but when it is one which can only occur in rare cases the value 8000 pounds per square inch may be used.

A long cap on a column is more conducive to the production of eccentricity of loading than a short one, hence a long cap is a source of weakness in a column.

**ULTIMATE STRENGTH OF WROUGHT-IRON COLUMNS.**

(Pottsville Iron and Steel Co.)

Computed by Gordon's formula,  $p = \frac{f}{1 + c\left(\frac{l}{r}\right)^2}$ .

$p$  = ultimate strength in lbs. per square inch;

$l$  = length of column in inches;

$r$  = least radius of gyration in inches;

$f$  = 40,000;

$C$  = 1/40,000 for square end-bearings; 1/30,000 for one pin and one square bearing; 1/20,000 for two pin-bearings.

For safe working load on these columns use a factor of 4 when used in buildings, or when subjected to dead load only; but when used in bridges the factor should be 5.

**Maximum Permissible Stresses** in columns used in buildings. (Building Ordinances of City of Chicago, 1893.)

For riveted or other forms of wrought-iron columns:

$S = \frac{12000a}{1 + \frac{l^2}{36000r^2}}$ .  $l$  = length of column in inches;  
 $r$  = least radius of gyration in inches;  
 $a$  = area of column in square inches.

For riveted or other steel columns, if more than  $60r$  in length:

$S = 17,000 - \frac{60l}{r}$ .

If less than  $60r$  in length:  $S = 13,500a$ .

For wooden posts:

$S = \frac{ac}{1 + \frac{l^2}{250d^2}}$ .  $a$  = area of post in square inches;  
 $d$  = least side of rectangular post in inches;  
 $l$  = length of post in inches;  
 $c = \begin{cases} 600 & \text{for white or Norway pine;} \\ 800 & \text{for oak;} \\ 900 & \text{for long-leaf yellow pine.} \end{cases}$

**BUILT COLUMNS.**

From experiments by T. D. Lovett, discussed by Burr, the values of  $f$  and  $a$  in several cases are determined, giving empirical forms of Gordon's formula as follows:  $p$  = pounds crushing strength per square inch of section,  $l$  = length of column in inches,  $r$  = radius of gyration in inches.

With great variations of stress a factor of safety of as high as 6 or 8 may be used, or it may be as low as 3 or 4, if the condition of stress is uniform or essentially so.

Burr gives the following general principles which govern the resistance of built columns :

The material should be disposed as far as possible from the neutral axis of the cross-section, thereby increasing  $r$ ;

There should be no initial internal stress;

The individual portions of the column should be mutually supporting;

The individual portions of the column should be so firmly secured to each other that no relative motion can take place, in order that the column may fail as a whole, thus maintaining the original value of  $r$ .

Stoney says: "When the length of a rectangular wrought-iron tubular column does not exceed 30 times its least breadth, it fails by the bulging or buckling of a short portion of the plates, not by the flexure of the pillar as a whole."

In Trans. A. S. C. E., Oct. 1880, are given the following formulæ for the ultimate resistance of wrought-iron columns designed by C. Shaler Smith :

**Flat Ends.**

Square Column.	Phoenix Column.	American Bridge Co. Column.	Common Column.
$p = \frac{38,500}{1 + \frac{1}{5820} \frac{l^2}{d^2}} \quad (12)$	$\frac{42,500}{1 + \frac{1}{4500} \frac{l^2}{d^2}} \quad (15)$	$\frac{36,500}{1 + \frac{1}{3750} \frac{l^2}{d^2}} \quad (18)$	$\frac{36,500}{1 + \frac{1}{2700} \frac{l^2}{d^2}} \quad (21)$

**One Pin End.**

$p = \frac{38,500}{1 + \frac{1}{3000} \frac{l^2}{d^2}} \quad (13)$	$\frac{40,000}{1 + \frac{1}{2250} \frac{l^2}{d^2}} \quad (16)$	$\frac{36,500}{1 + \frac{1}{2250} \frac{l^2}{d^2}} \quad (19)$	$\frac{36,500}{1 + \frac{1}{1500} \frac{l^2}{d^2}} \quad (22)$
--	--	--	--

**Two Pin Ends.**

$p = \frac{37,500}{1 + \frac{1}{1900} \frac{l^2}{d^2}} \quad (14)$	$\frac{36,600}{1 + \frac{1}{1500} \frac{l^2}{d^2}} \quad (17)$	$\frac{36,500}{1 + \frac{1}{1750} \frac{l^2}{d^2}} \quad (20)$	$\frac{36,500}{1 + \frac{1}{1200} \frac{l^2}{d^2}} \quad (23)$
--	--	--	--

The "common" column consists of two channels, opposite, with flanges outward, with a plate on one side and a lattice on the other.

The formula for "square" columns may be used without much error for the common-chord section composed of two channel-bars and plates, with the axis of the pin passing through the centre of gravity of the cross-section. (Burr).

Compression members composed of two channels connected by zigzag bracing may be treated by formulæ 4 and 5, using  $f = 36,000$  instead of 39,000.

Experiments on full-sized Phoenix columns in 1873 showed a close agreement of the results with formulæ 6-8. Experiments on full-sized Phoenix columns on the Watertown testing-machine in 1881 showed considerable discrepancies when the value of  $l \div r$  became comparatively small. The following modified form of Gordon's formula gave tolerable results through the whole range of experiments :

Phoenix columns, flat end, 
$$p = \frac{40,000 \left( 1 + \frac{2r}{l} \right)}{1 + \frac{50,000}{r^2}} \dots \dots \dots (24)$$

Plotting results of three series of experiments on Phoenix columns, a more simple formula than Gordon's is reached as follows :

Phoenix columns, flat ends,  $p = 39,640 - 46 \frac{l}{r}$ , when  $l \div r$  is from 30 to 140;  

$$p = 64,700 - 4600 \sqrt{\frac{l}{r}}$$
 when  $l \div r$  is less than 30.

**Dimensions of Phoenix Columns.**

(Phoenix Iron Co.)

The dimensions are subject to slight variations, which are unavoidable in rolling iron shapes.

The weights of columns given are those of the 4, 6, or 8 segments of which they are composed. The *rivet heads* add from 2% to 5% to the weights given. Rivets are spaced 3, 4, or 6 in. apart from centre to centre, and somewhat more closely at the ends than towards the centre of the column.

G columns have 8 segments, E columns 6 segments, C, B<sup>2</sup>, B<sup>1</sup>, and A have 4 segments. *Least radius of gyration* =  $D \times .3636$ .

The safe loads given are computed as being one-fourth of the breaking load, and as producing a maximum stress, in an axial direction, on a square-end column of not more than 14,000 lbs. per sq. in. for lengths of 90 radii and under.

**Dimensions of Phoenix Steel Columns.**

(Least radius of gyration equals  $D \times .3636$ .)

**Working Formulæ for Wrought-iron and Steel Struts of various Forms.**—Burr gives the following practical formulæ, which he believes to possess advantages over Gordon's:

Kind of Strut.	<i>p</i> = Ultimate Strength, lbs. per sq. in. of Section.	<i>p</i> <sub>1</sub> = Working Strength = 1/5 Ultimate, lbs. per sq. in. of Section.
Flat and fixed end iron angles and tees	44000 - 140 $\frac{l}{r}$ (1)	8800 - 28 $\frac{l}{r}$ (2)
Hinged-end iron angles and tees.....	46000 - 175 $\frac{l}{r}$ (3)	9200 - 35 $\frac{l}{r}$ (4)
Flat-end iron channels and I beams....	40000 - 110 $\frac{l}{r}$ (5)	8000 - 22 $\frac{l}{r}$ (6)
Flat-end mild-steel angles.....	52000 - 180 $\frac{l}{r}$ (7)	10400 - 36 $\frac{l}{r}$ (8)
Flat-end high-steel angles.....	76000 - 290 $\frac{l}{r}$ (9)	15200 - 58 $\frac{l}{r}$ (10)
Pin-end solid wrought-iron columns....	32000 - 80 $\frac{l}{r}$ } (11)	6400 - 16 $\frac{l}{r}$ } (12)
	32000 - 277 $\frac{l}{d}$ }	6400 - 55 $\frac{l}{d}$ }
Equations (1) to (4) are to be used only between	$\frac{l}{r} = 40$ and	$\frac{l}{r} = 200$
“ (5) and (6) “ “ “ “ “ “	“ = 20 “ “ = 200	
“ (7) to (10) “ “ “ “ “ “	“ = 40 “ “ = 200	
“ (11) and (12) “ “ “ “ “ “	“ = 20 “ “ = 200	
	or $\frac{l}{d} = 6$ and	$\frac{l}{d} = 65$

Steel columns, properly made, of steel ranging in specimens from 65,000 to 73,000 lbs. per square inch should give a resistance 25 to 33 per cent in excess of that of wrought-iron columns with the same value of *l* + *r*, provided that ratio does not exceed 140.

The unsupported width of a plate in a compression member should not exceed 30 times its thickness.

In built columns the transverse distance between centre lines of rivets securing plates to angles or channels, etc., should not exceed 35 times the plate thickness. If this width is exceeded, longitudinal buckling of the

plate takes place, and the column ceases to fail as a whole, but yields in detail.

The same tests show that the thickness of the leg of an angle to which latticing is riveted should not be less than 1/9 of the length of that leg or side if the column is purely and wholly a compression member. The above limit may be passed somewhat in stiff ties and compression members designed to carry transverse loads.

The panel points of latticing should not be separated by a greater distance than 60 times the thickness of the angle-leg to which the latticing is riveted, if the column is wholly a compression member.

The rivet pitch should never exceed 16 times the thickness of the thinnest metal pierced by the rivet, and if the plates are very thick it should never be nearly equal that value.

**Merriman's Rational Formula for Columns** (*Eng. News*, July 19, 1894).

$$C = \frac{B}{1 - \frac{nB}{\pi^2 E} \frac{l^2}{r^2}} \dots \dots \dots (1)$$

$$B = \frac{C}{1 + \frac{nC}{\pi^2 E} \frac{l^2}{r^2}} \dots \dots \dots (2)$$

$B$  = unit-load on the column = total load  $P \div$  area of cross-section  $A$ ;  
 $C$  = maximum compressive unit-stress on the concave side of the column;  
 $l$  = length of the column;  $r$  = least radius of gyration of the cross-section  
 $E$  = coefficient of elasticity of the material;  $n = 1$  for both ends round.  
 $n = 4/9$  for one end round and one fixed;  $n = 1/4$  for both ends fixed. This formula is for use with strains within the elastic limit only: it does not hold good when the strain  $C$  exceeds the elastic limit.

Prof. Merriman takes the mean value of  $E$  for timber = 1,500,000, for cast iron = 15,000,000, for wrought-iron = 25,000,000, and for steel = 30,000,000, and  $\pi^2 = 10$  as a close enough approximation. With these values he computes the following tables from formula (1):

**I.—Wrought-iron Columns with Round Ends.**

Unit-load. $\frac{P}{A}$ or $B$ .	Maximum Compressive Unit-stress $C$ .							
	$\frac{l}{r} = 20$	$\frac{l}{r} = 40$	$\frac{l}{r} = 60$	$\frac{l}{r} = 80$	$\frac{l}{r} = 100$	$\frac{l}{r} = 120$	$\frac{l}{r} = 140$	$\frac{l}{r} = 160$

14,000	14,070	14,250	14,610	15,130	15,850	16,830	18,150	19,960
15,000	15,080	15,310	15,710	16,310	17,140	18,290	19,870	22,060

The design of the cross-section of a column to carry a given load with maximum unit-stress  $C$  may be made by assuming dimensions, and then

computing  $C$  by formula (1). If the agreement between the specified and computed values is not sufficiently close, new dimensions must be chosen, and the computation be repeated. By the use of the above tables the work will be shortened.

The formula (1) may be put in another form which in some cases will abbreviate the numerical work. For  $B$  substitute its value  $P \div A$ , and for  $Ar^2$  write  $I$ , the least moment of inertia of the cross-section; then

$$I - \frac{P}{C}r^2 = \frac{nPl^2}{\pi^2 E}, \dots \dots \dots (3)$$

In which  $I$  and  $r^2$  are to be determined.

For example, let it be required to find the size of a square oak column with fixed ends when loaded with 24,000 lbs. and 16 ft. long, so that the maximum compressive stress  $C$  shall be 1000 lbs. per square inch. Here  $I = 24,000$ ,  $C = 1000$ ,  $n = \frac{1}{4}$ ,  $\pi^2 = 10$ ,  $E = 1,500,000$ ,  $l = 16 \times 12$ , and (3) becomes

$$I - 24r^2 = 14.75.$$

Now let  $x$  be the side of the square; then

$$I = \frac{x^4}{12} \quad \text{and} \quad r^2 = \frac{x^2}{12},$$

so that the equation reduces to  $x^4 - 24x^2 = 177$ , from which  $x^2$  is found to be 29.92 sq. in., and the side  $x = 5.47$  in. Thus the unit-load  $B$  is about 802 lbs. per square inch.

### WORKING STRAINS ALLOWED IN BRIDGE MEMBERS.

Theodore Cooper gives the following in his Bridge Specifications :

Compression members shall be so proportioned that the maximum load shall in no case cause a greater strain than that determined by the following formula :

$$P = \frac{8000}{1 + \frac{l^2}{40,000r^2}} \text{ for square-end compression members ;}$$

$$P = \frac{8000}{1 + \frac{l^2}{30,000r^2}} \text{ for compression members with one pin and one square end ;}$$

$$P = \frac{8000}{1 + \frac{l^2}{20,000r^2}} \text{ for compression members with pin-bearings ;}$$

(These values may be increased in bridges over 150 ft. span. See Cooper's Specifications.)

$P$  = the allowed compression per square inch of cross-section;

$l$  = the length of compression member, in inches;

$r$  = the least radius of gyration of the section in inches.

No compression member, however, shall have a length exceeding 45 times its least width.

*Tension Members.*—All parts of the structure shall be so proportioned that the maximum loads shall in no case cause a greater tension than the following (except in spans exceeding 150 feet) :

	Pounds per sq. in.
On lateral bracing.....	15,000
On solid rolled beams, used as cross floor-beams and stringers.....	9,000
On bottom chords and main diagonals (forged eye-bars).....	10,000
On bottom chords and main diagonals (plates or shapes), net section.....	8,000
On counter rods and long verticals (forged eye-bars).....	8,000
On counter and long verticals (plates or shapes), net section..	6,500
On bottom flange of riveted cross-girders, net section .....	8,000
On bottom flange of riveted longitudinal plate girders over 20 ft. long, net section.....	8,000

- On bottom flange of riveted longitudinal plate girders under 20 ft. long, net section ..... 7,000
- On floor-beam hangers, and other similar members liable to sudden loading (bar iron with forged ends)..... 6,000
- On floor-beam hangers, and other similar members liable to sudden loading (plates or shapes), net section..... 5,000

Members subject to alternate strains of tension and compression shall be proportioned to resist each kind of strain. Both of the strains shall, however, be considered as increased by an amount equal to 8/10 of the least of the two strains, for determining the sectional area by the above allowed strains.

The Phoenix Bridge Co. (Standard Specifications, 1895) gives the following :

The greatest working stresses in pounds per square inch shall be as follows :

*Tension.*

Steel.		Iron.
$P = 9,000 \left[ 1 + \frac{\text{Min. stress}}{\text{Max. stress}} \right]$	For bars, forged ends.	$P = 7,500 \left[ 1 + \frac{\text{Min. stress}}{\text{Max. stress}} \right]$
$P = 8,500 \left[ 1 + \frac{\text{Min. stress}}{\text{Max. stress}} \right]$	Plates or shapes net.	$P = 7,000 \left[ 1 + \frac{\text{Min. stress}}{\text{Max. stress}} \right]$
8,500 pounds.	Floor-beam hangers, forged ends.....	7,000 pounds.
7,500 " "	Floor-beam hangers, plates or shapes, net section.....	6,000 " "
10,000 " "	Lower flanges of rolled beams.....	8,000 " "
20,000 " "	Outside fibres of pins.....	15,000 " "
20,000 " "	Pins for wind-bracing.....	22,500 " "
20,000 " "	Lateral bracing.....	15,000 " "

*Shearing.*

- 9,000 pounds. Pins and rivets..... 7,500 pounds.
- Hand-driven rivets 20% less unit stresses. For bracing increase unit stresses 50%.
- 6,000 pounds. Webs of plate girders..... 5,000 pounds.

*Bearing.*

- 16,000 pounds. Projection semi-intrados pins and rivets.... 12,000 pounds.
- Hand-driven rivets 20% less unit stresses. For bracing increase unit stresses 50%.

*Compression.*

Lengths less than forty times the least radius of gyration, *P* previously found. See Tension.

Lengths more than forty times the least radius of gyration, *P* reduced by following formulæ:

For both ends fixed, 
$$b = \frac{P}{1 + \frac{l^2}{36,000 r^2}}$$

For one end hinged, 
$$b = \frac{P}{1 + \frac{l^2}{24,000 r^2}}$$

For both ends hinged, 
$$b = \frac{P}{1 + \frac{l^2}{18,000 r^2}}$$

*P* = permissible stress previously found (see Tension); *b* = allowable working stress per square inch; *l* = length of member in inches; *r* = least radius of gyration of section in inches. No compression member, however, shall have a length exceeding 45 times its least width.

	Pounds per sq. in.
In counter web members.....	10,500
In long verticals....	10,000
In all main-web and lower-chord eye-bars.....	13,200
In plate hangers (net section).....	9,000
In tension members of lateral and transverse bracing.....	19,000
In steel-angle lateral ties (net section)....	15,000

For spans over 200 feet in length the greatest allowed working stresses per square inch, in lower-chord and end main-web eye-bars, shall be taken at

$$10,000 \left( 1 + \frac{\text{min. total stress}}{\text{max. total stress}} \right)$$

whenever this quantity exceeds 13,200.

The greatest allowable stress in the main-web eye-bars nearest the centre of such spans shall be taken at 13,200 pounds per square inch ; and those for the intermediate eye-bars shall be found by direct interpolation between the preceding values.

The greatest allowable working stresses in steel plate and lattice girders and rolled beams shall be taken as follows :

	Pounds per sq. in.
Upper flange of plate girders (gross section).....	10,000
Lower flange of plate girders (net section).....	10,000
In counters and long verticals of lattice girders (net section) ..	9,000
In lower chords and main diagonals of lattice girders (net section).....	10,000
In bottom flanges of rolled beams.....	10,000
In top flanges of rolled beams.....	10,000

### RESISTANCE OF HOLLOW CYLINDERS TO COLLAPSE.

Fairbairn's empirical formula (*Phil. Trans.* 1858) is

$$p = 9,675,600 \frac{t^{2.19}}{ld}, \dots \dots \dots (1)$$

where  $p$  = pressure in lbs. per square inch,  $t$  = thickness of cylinder,  $d$  = diameter, and  $l$  = length, all in inches ; or,

$$p = 806,300 \frac{t^{2.19}}{Ld}, \text{ if } L \text{ is in feet. } \dots \dots \dots (2)$$

He recommends the simpler formula

$$p = 9,675,600 \frac{t^2}{ld} \dots \dots \dots (3)$$

as sufficiently accurate for practical purposes, for tubes of considerable diameter and length.

The diameters of Fairbairn's experimental tubes were 4", 6", 8", 10", and 12", and their lengths, between the cast-iron ends, ranged between 19 inches and 60 inches.

His formula (3) has been generally accepted as the basis of rules for ascertaining the strength of boiler-flues. In some cases, however, limits are fixed to its application by a supplementary formula.

Lloyd's Register contains the following formula for the strength of circular boiler-flues, viz.,

$$P = \frac{89,600t^2}{Ld} \dots \dots \dots (4)$$

The English Board of Trade prescribes the following formula for circular flues, when the longitudinal joints are welded, or made with riveted butt-straps, viz.,

$$P = \frac{90,000t^2}{(L+1)d} \dots \dots \dots (5)$$

For lap-joints and for inferior workmanship the numerical factor may be reduced as low as 60,000.

The rules of Lloyd's Register, as well as those of the Board of Trade, prescribe further, that in no case the value of  $P$  must exceed the amount given by the following equation, viz.,

$$P = \frac{8000t}{d} \dots \dots \dots (6)$$

In formulæ (4), (5), (6)  $P$  is the highest working pressure in pounds per square inch,  $t$  and  $d$  are the thickness and diameter in inches,  $L$  is the length of the flue in feet measured between the strengthening rings, in case it is fitted with such. Formula (4) is the same as formula (3), with a factor of safety of 9. In formula (5) the length  $L$  is increased by 1; the influence which this addition has on the value of  $P$  is, of course, greater for short tubes than for long ones.

Nystrom has deduced from Fairbairn's experiments the following formula for the collapsing strength of flues :

$$p = \frac{4Tt^2}{d\sqrt{L}}, \dots \dots \dots (7)$$

where  $p$ ,  $t$ , and  $d$  have the same meaning as in formula (1),  $L$  is the length in feet, and  $T$  is the tensile strength of the metal in pounds per square inch.

If we assign to  $T$  the value 50,000, and express the length of the flue in inches, equation (7) assumes the following form, viz.,

$$p = 692,800 \frac{t^2}{d\sqrt{l}} \dots \dots \dots (8)$$

Nystrom considers a factor of safety of 4 sufficient in applying his formula. (See "A New Treatise on Steam Engineering," by J. W. Nystrom, p. 106.)

Formula (1), (4), and (8) have the common defect that they make the collapsing pressure decrease indefinitely with increase of length, and *vice versa*. M. Love has deduced from Fairbairn's experiments an equation of a different form, which, reduced to English measures, is as follows, viz.,

$$p = 5,358,150 \frac{t^2}{ld} + 41,906 \frac{t^2}{d} + 1323 \frac{t}{d}, \dots \dots \dots (9)$$

where the notation is the same as in formula (1).

D. K. Clark, in his "Manual of Rules," etc., p. 696, gives the dimensions of six flues, selected from the reports of the Manchester Steam-Users Association, 1862-69, which collapsed while in actual use in boilers. These flues varied from 24 to 60 inches in diameter, and from 3-16 to 3/8 inch in thickness. They consisted of rings of plates riveted together, with one or two longitudinal seams, but all of them unfortified by intermediate flanges or strengthening rings. At the collapsing pressures the flues experienced compressions ranging from 1.53 to 2.17 tons, or a mean compression of 1.82 tons per square inch of section. From these data Clark deduced the following formula "for the average resisting force of common boiler-flues," viz.,

$$p = t^2 \left( \frac{50,000}{d} - 500 \right), \dots \dots \dots (10)$$

where  $p$  is the collapsing pressure in pounds per square inch, and  $d$  and  $t$  are the diameter and thickness expressed in inches.

C. R. Roelker, in *Van Nostrand's Magazine*, March, 1881, discussing the above and other formulæ, shows that experimental data are as yet insufficient to determine the value of any of the formulæ. He says that Nystrom's formula, (8), gives a closer agreement of the calculated with the actual collapsing pressures in experiments on flues of every description than any of the other formulæ.

**Collapsing Pressure of Plain Iron Tubes or Flues.**

(Clark, S. E., vol. i. p. 643.)

The resistance to collapse of plain-riveted flues is directly as the square of the thickness of the plate, and inversely as the square of the diameter. The support of the two ends of the flue does not practically extend over a length of tube greater than twice or three times the diameter. The collapsing pressure of long tubes is therefore practically independent of the length.

Instances of collapsed flues of Cornish and Lancashire boilers collated by Clark, showed that the resistance to collapse of flues of  $\frac{3}{8}$ -inch plates, 18 to 43 feet long, and 30 to 50 inches diameter, varied as the 1.75 power of the diameter. Thus,

for diameters of.....	30	35	40	45	50	inches,
the collapsing pressures were.....	76	58	45	37	30	lbs. per sq. in;
for 7-16-inch plates the collapsing pressures were.....	..	..	60	49	42	“ “ “

For collapsing pressures of plain iron flue-tubes of Cornish and Lancashire steam-boilers, Clark gives:

$$P = \frac{200,000t^2}{d^{1.75}}$$

- $P$  = collapsing pressure, in pounds per square inch;
- $t$  = thickness of the plates of the furnace tube, in inches.
- $d$  = internal diameter of the furnace tube, in inches.

For short lengths the longitudinal tensile resistance may be effective in augmenting the resistance to collapse. Flues efficiently fortified by flange-joints or hoops at intervals of 3 feet may be enabled to resist from 50 lbs. to 60 lbs. or 70 lbs. pressure per square inch more than plain tubes, according to the thickness of the plates.

**Strength of Small Tubes.**—The collapsing resistance of solid-drawn tubes of small diameter, and from .134 inch to .109 inch in thickness, has been tested experimentally by Messrs. J. Russell & Sons. The results for wrought-iron tubes varied from 14.33 to 20.07 tons per square-inch section of the metal, averaging 18.20 tons, as against 17.57 to 24.28 tons, averaging 22.40 tons, for the bursting pressure.

(For strength of Segmental Crowns of Furnaces and Cylinders see Clark, S. E., vol. i, pp. 649-651 and pp. 627, 628.)

**Formula for Corrugated Furnaces** (*Eng'g*, July 24, 1891, p. 102).—As the result of a series of experiments on the resistance to collapse of Fox's corrugated furnaces, the Board of Trade and Lloyd's Registry altered their formulæ for these furnaces in 1891 as follows:

Board of Trade formula is altered from

$$\frac{12,500 \times T}{D} = WP \text{ to } \frac{14,000 \times T}{D} = WP.$$

- $T$  = thickness in inches;
- $D$  = mean diameter of furnace;
- $WP$  = working pressure in pounds per square inch.

Lloyd's formula is altered from

$$\frac{1000 \times (T - 2)}{D} = WP \text{ to } \frac{1234 \times (T - 2)}{D} = WP.$$

- $T$  = thickness in sixteenths of an inch;
- $D$  = greatest diameter of furnace;
- $WP$  = working pressure in pounds per square inch.

### TRANSVERSE STRENGTH.

In transverse tests the strength of bars of rectangular section is found to vary directly as the breadth of the specimen tested, as the square of its depth, and inversely as its length. The deflection under any load varies as the cube of the length, and inversely as the breadth and as the cube of the depth. Represented algebraically, if  $S$  = the strength and  $D$  the deflection,  $l$  the length,  $b$  the breadth, and  $d$  the depth,

$$S \text{ varies as } \frac{bd^2}{l} \text{ and } D \text{ varies as } \frac{l^3}{bd^3}.$$

For the purpose of reducing the strength of pieces of various sizes to a common standard, the term *modulus of rupture* (represented by  $R$ ) is used. Its value is obtained by experiment on a bar of rectangular section

supported at the ends and loaded in the middle and substituting numerical values in the following formula :

$$R = \frac{3}{2} \frac{Pl}{bd^2},$$

in which  $P$  = the breaking load in pounds,  $l$  = the length in inches,  $b$  the breadth, and  $d$  the depth.

The *modulus of rupture* is sometimes defined as the strain at the instant of rupture upon a unit of the section which is most remote from the neutral axis on the side which first ruptures. This definition, however, is based upon a theory which is yet in dispute among authorities, and it is better to define it as a numerical value, or experimental constant, found by the application of the formula above given.

From the above formula, making  $l$  12 inches, and  $b$  and  $d$  each 1 inch, it follows that the modulus of rupture is 18 times the load required to break a bar one inch square, supported at two points one foot apart, the load being applied in the middle.

$$\begin{aligned} \text{Coefficient of transverse strength} &= \frac{\text{span in feet} \times \text{load at middle in lbs.}}{\text{breadth in inches} \times (\text{depth in inches})^2} \\ &= \frac{1}{18} \text{th of the modulus of rupture.} \end{aligned}$$

**Fundamental Formulæ for Flexure of Beams** (Merriman).

Resisting shear = vertical shear;

Resisting moment = bending moment;

Sum of tensile stresses = sum of compressive stresses;

Resisting shear = algebraic sum of all the vertical components of the internal stresses at any section of the beam.

If  $A$  be the area of the section and  $S_s$  the shearing unit stress, then resisting shear =  $AS_s$ ; and if the vertical shear =  $V$ , then  $V = AS_s$ .

The *vertical shear* is the algebraic sum of all the external vertical forces on one side of the section considered. It is equal to the reaction of one support, considered as a force acting upward, minus the sum of all the vertical downward forces acting between the support and the section.

The *resisting moment* = algebraic sum of all the moments of the internal horizontal stresses at any section with reference to a point in that section, =  $\frac{SI}{c}$ , in which  $S$  = the horizontal unit stress, tensile or compressive

as the case may be, upon the fibre most remote from the neutral axis,  $c$  = the shortest distance from that fibre to said axis, and  $I$  = the moment of inertia of the cross-section with reference to that axis.

The *bending moment*  $M$  is the algebraic sum of the moment of the external forces on one side of the section with reference to a point in that section = moment of the reaction of one support minus sum of moments of loads between the support and the section considered.

$$M = \frac{SI}{c}$$

The bending moment is a compound quantity = product of a force by the distance of its point of application from the section considered, the distance being measured on a line drawn from the section perpendicular to the direction of the action of the force.

Concerning the above formula, Prof. Merriman, *Eng. News*, July 21, 1894, says: The formula just quoted is true when the unit-stress  $S$  on the part of the beam farthest from the neutral axis is within the elastic limit of the material. It is not true when this limit is exceeded, because then the neutral axis does not pass through the centre of gravity of the cross-section, and because also the different longitudinal stresses are not proportional to their distances from that axis, these two requirements being involved in the deduction of the formula. But in all cases of design the permissible unit-stresses should not exceed the elastic limit, and hence the formula applies rationally, without regarding the ultimate strength of the material or any of the circumstances regarding rupture. Indeed so great reliance is placed upon this formula that the practice of testing beams by rupture has been almost entirely abandoned, and the allowable unit-stresses are mainly derived from tensile and compressive tests.

**GENERAL FORMULÆ FOR TRANSVERSE STRENGTH OF BEAMS OF UNIFORM CROSS-SECTION.**

Beam.	Rectangular Beam.		Beam of any Section.		
	Breaking Load.	Deflection for Load $P$ or $W$ .	Maximum Moment of Stress.	Moment of Rupture.	Deflection. $\Delta$
Fixed at one end, load at the other.....	$P = \frac{1}{6} \frac{Rbd^2}{l}$	$\frac{4Pl^3}{Ebd^3}$	$Pl =$	$\frac{RI}{c}$	$\frac{1}{3} \frac{Pl^3}{EI}$
Same with load distributed uniformly.....	$W = \frac{1}{3} \frac{Rbd^2}{l}$	$\frac{3}{2} \frac{Wl^3}{Ebd^3}$	$\frac{1}{2} Wl =$	$\frac{RI}{c}$	$\frac{1}{8} \frac{Wl^3}{EI}$
Supported at ends, loaded in middle.....	$P = \frac{2}{3} \frac{Rbd^2}{l}$	$\frac{Pl^3}{4Ebd^3}$	$\frac{1}{4} Pl =$	$\frac{RI}{c}$	$\frac{1}{48} \frac{Pl^3}{EI}$
Same loaded uniformly.....	$W = \frac{4}{3} \frac{Rbd^2}{l}$	$\frac{5}{32} \frac{Wl^3}{Ebd^3}$	$\frac{1}{8} Wl =$	$\frac{RI}{c}$	$\frac{5}{384} \frac{Wl^3}{EI}$
Same, loaded at middle, and also with uniform load, }.....	$2P + W = \frac{4}{3} \frac{Rbd^2}{l}$	$\frac{1}{4} \left( P + \frac{1}{8} W \right) \frac{l^3}{Ebd^3}$	$\left( \frac{1}{4} P + \frac{1}{8} W \right) l =$	$\frac{RI}{c}$	$\frac{1}{48} \left( P + \frac{5}{8} W \right) \frac{l^3}{EI}$
Fixed at both ends, loaded in middle.....	$P = \frac{4}{3} \frac{Rbd^2}{l}$	$\frac{1}{16} \frac{Pl^3}{Ebd^3}$	$\frac{1}{8} Pl =$	$\frac{RI}{c}$	$\frac{Pl^3}{192 EI}$
Same, Barlow's Experiments.....	$P = \frac{Rbd^2}{l}$		$\frac{1}{6} Pl =$	$\frac{RI}{c}$	
Same, uniformly loaded.....	$W = \frac{2Rbd^2}{l}$	$\frac{1}{32} \frac{Wl^3}{Ebd^3}$	$\frac{1}{12} Wl =$	$\frac{RI}{c}$	$\frac{Wl^3}{384 EI}$
Fixed at one end, supported at the other, loaded at .634 $l$ from fixed end, }.....		$\frac{.1148Pl^3}{Ebd^3}$	$\frac{3}{8} \left( 2 \sqrt{3-3} \right) Pl =$	$\frac{RI}{c}$	$\frac{Pl^3}{105 EI}$ (nearly).
Same uniformly loaded.....	$W = \frac{4}{3} \frac{Rbd^2}{l}$	$\frac{.0648Wl^3}{Ebd^3}$	$\frac{1}{8} Wl =$	$\frac{RI}{c}$	$\frac{Wl^3}{185 EI}$ (nearly).

**Formulae for Transverse Strength of Beams.**—Referring to table on preceding page,

$P$  = load at middle;

$W$  = total load, distributed uniformly;

$l$  = length,  $b$  = breadth,  $d$  = depth, in inches;

$E$  = modulus of elasticity;

$R$  = modulus of rupture, or stress per square inch of extreme fibre;

$I$  = moment of inertia;

$c$  = distance between neutral axis and extreme fibre.

For breaking load of circular section, replace  $bd^2$  by  $0.59d^3$ .

For good wrought iron the value of  $R$  is about 80,000, for steel about 120,000, the percentage of carbon apparently having no influence. (Thurston, Iron and Steel, p. 491).

For cast iron the value of  $R$  varies greatly according to quality. Thurston found 45,740 and 67,980 in No. 2 and No. 4 cast iron, respectively.

For beams fixed at both ends and loaded in the middle, Barlow, by experiment, found the maximum moment of stress =  $1/6Pl$  instead of  $1/8Pl$ , the result given by theory. Prof. Wood (Resist. Mats. p. 155) says of this case: The phenomena are of too complex a character to admit of a thorough and exact analysis, and it is probably safer to accept the results of Mr. Barlow in practice than to depend upon theoretical results.

**APPROXIMATE GREATEST SAFE LOADS IN LBS. ON STEEL BEAMS.** (Pencoyd Iron Works.)

Based on fibre strains of 16,000 lbs. for steel. (For iron the loads should be one-eighth less, corresponding to a fibre strain of 14,000 lbs. per square inch.)

$L$  = length in feet between supports;

$a$  = interior area in square inches;

$A$  = sectional area of beam in square inches;

$d$  = interior depth in inches.

$D$  = depth of beam in inches.

$w$  = working load in net tons.

Shape of Section.	Greatest Safe Load in Pounds.		Deflection in Inches.	
	Load in Middle.	Load Distributed.	Load in Middle.	Load Distributed.
Solid Rect-angle.	$\frac{890AD}{L}$	$\frac{1780AD}{L}$	$\frac{wL^3}{32AD^2}$	$\frac{wL^3}{52AD^2}$
Hollow Rect-angle.	$\frac{890(AD-ad)}{L}$	$\frac{1780(AD-ad)}{L}$	$\frac{wL^3}{32(AD^2-ad^2)}$	$\frac{wL^3}{52(AD^2-ad^2)}$
Solid Cylinder.	$\frac{667AD}{L}$	$\frac{1333AD}{L}$	$\frac{wL^3}{24AD^2}$	$\frac{wL^3}{38AD^2}$
Hollow Cylinder.	$\frac{667(AD-ad)}{L}$	$\frac{1333(AD-ad)}{L}$	$\frac{wL^3}{24(AD^2-ad^2)}$	$\frac{wL^3}{38(AD^2-ad^2)}$
Even-legged Angle or Tee.	$\frac{885AD}{L}$	$\frac{1770AD}{L}$	$\frac{wL^3}{32AD^2}$	$\frac{wL^3}{52AD^2}$
Channel or Z bar.	$\frac{1525AD}{L}$	$\frac{3050AD}{L}$	$\frac{wL^3}{53AD^2}$	$\frac{wL^3}{85AD^2}$
Deck Beam.	$\frac{1380AD}{L}$	$\frac{2760AD}{L}$	$\frac{wL^3}{50AD^2}$	$\frac{wL^3}{80AD^2}$
I Beam.	$\frac{1695AD}{L}$	$\frac{3390AD}{L}$	$\frac{wL^3}{58AD^2}$	$\frac{wL^3}{98AD^2}$
I	II	III	IV	V

The above formulæ for the strength and stiffness of rolled beams of various sections are intended for convenient application in cases where strict accuracy is not required.

The rules for rectangular and circular sections are correct, while those for the flanged sections are approximate, and limited in their application to the standard shapes as given in the Pencoyd tables. When the section of any beam is increased above the standard minimum dimensions, the flanges remaining unaltered, and the web alone being thickened, the tendency will be for the load as found by the rules to be in excess of the actual; but within the limits that it is possible to vary any section in the rolling, the rules will apply without any serious inaccuracy.

The calculated safe loads will be approximately one half of loads that would injure the elasticity of the materials.

The rules for deflection apply to any load below the elastic limit, or less than double the greatest safe load by the rules.

If the beams are long without lateral support, reduce the loads for the ratios of width to span as follows:

Length of Beam.	Proportion of Calculated Load forming Greatest Safe Load.	
20 times flange width.	Whole calculated load.	
30 " " "	9-10	" "
40 " " "	8-10	" "
50 " " "	7-10	" "
60 " " "	6-10	" "
70 " " "	5-10	" "

These rules apply to beams supported at each end. For beams supported otherwise, alter the coefficients of the table as described below, referring to the respective columns indicated by number.

#### Changes of Coefficients for Special Forms of Beams.

Kind of Beam.	Coefficient for Safe Load.	Coefficient for Deflection.
Fixed at one end, loaded at the other.	One fourth of the coefficient, col. II.	One sixteenth of the coefficient of col. IV.
Fixed at one end, load evenly distributed.	One fourth of the coefficient of col. III.	Five forty-eighths of the coefficient of col. V.
Both ends rigidly fixed, or a continuous beam, with a load in middle.	Twice the coefficient of col. II.	Four times the coefficient of col. IV.
Both ends rigidly fixed, or a continuous beam, with load evenly distributed.	One and one-half times the coefficient of col. III.	Five times the coefficient of col. V.

#### ELASTIC RESILIENCE.

In a rectangular beam tested by transverse stress, supported at the ends and loaded in the middle,

$$P = \frac{2}{3} \frac{Rbd^2}{l};$$

$$\Delta = \frac{1}{4} \frac{Pl^3}{Ebd^3};$$

in which, if  $P$  is the load in pounds at the elastic limit,  $R$  = the modulus of transverse strength, or the strain on the extreme fibre, at the elastic limit,  $E$  = modulus of elasticity,  $\Delta$  = deflection,  $l$ ,  $b$ , and  $d$  = length, breadth, and depth in inches. Substituting for  $P$  in (2) its value in (1), we have

$$\Delta = \frac{1}{6} \frac{Rl^2}{Ed}.$$

# BEAMS OF UNIFORM STRENGTH THROUGHOUT LENGTH. 271

The elastic resilience = half the product of the load and deflection =  $\frac{1}{2}P\Delta$ , and the elastic resilience per cubic inch

$$= \frac{1}{2} \frac{P\Delta}{bd}$$

Substituting the values of  $P$  and  $\Delta$ , this reduces to elastic resilience per cubic inch =  $\frac{1}{18} \frac{R^2}{E}$ , which is independent of the dimensions; and therefore the elastic resilience per cubic inch for transverse strain may be used as a modulus expressing one valuable quality of a material.

Similarly for tension:

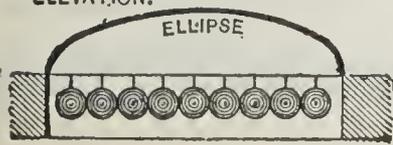

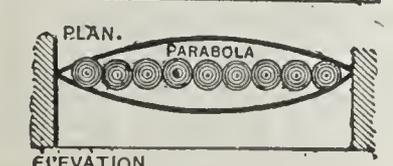

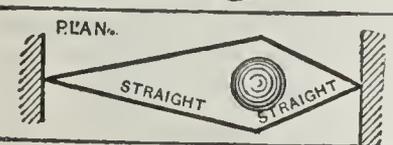

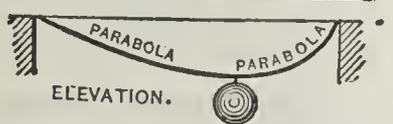

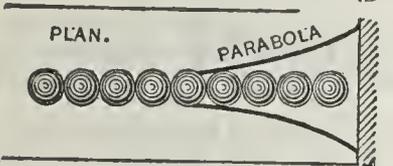

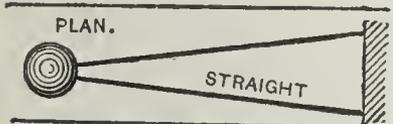

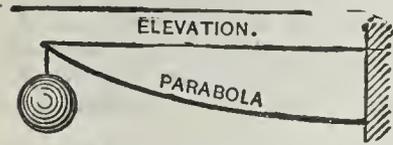

Let  $P$  = tensile stress in pounds per square inch at the elastic limit;  
 $e$  = elongation per unit of length at the elastic limit;  
 $E$  = modulus of elasticity =  $P \div e$ ; whence  $e = P \div E$ .

Then elastic resilience per cubic inch =  $\frac{1}{2}Pe = \frac{1}{2} \frac{P^2}{E}$ .

## BEAMS OF UNIFORM STRENGTH THROUGHOUT THEIR LENGTH.

The section is supposed in all cases to be rectangular throughout. The beams shown in plan are of uniform depth throughout. Those shown in elevation are of uniform breadth throughout.

$B$  = breadth of beam.  $D$  = depth of beam.

Fixed at one end, loaded at the other; curve parabola, vertex at loaded end;  $BD^2$  proportional to distance from loaded end. The beam may be reversed, so that the upper edge is parabolic, or both edges may be parabolic.

Fixed at one end, loaded at the other; triangle, apex at loaded end;  $BD^2$  proportional to the distance from the loaded end.

Fixed at one end; load distributed; triangle, apex at unsupported end;  $BD^2$  proportional to square of distance from unsupported end.

Fixed at one end; load distributed; curves two parabolas, vertices touching each other at unsupported end;  $BD^2$  proportional to distance from unsupported end.

Supported at both ends; load at any one point; two parabolas, vertices at the points of support, bases at point loaded;  $BD^2$  proportional to distance from nearest point of support. The upper edge or both edges may also be parabolic.

Supported at both ends; load at any one point; two triangles, apices at points of support, bases at point loaded;  $BD^2$  proportional to distance from the nearest point of support.

Supported at both ends; load distributed; curves two parabolas, vertices at the middle of the beam; bases centre line of beam;  $BD^2$  proportional to product of distances from points of support.

Supported at both ends; load distributed; curve semi-ellipse;  $BD^2$  proportional to the product of the distances from the points of support.

**PROPERTIES OF ROLLED STRUCTURAL STEEL.****Explanation of Tables of the Properties of I Beams, Channels, Angles, Deck-Beams, Bulb Angles, Z Bars, Tees, Trough and Corrugated Plates.**

(The Carnegie Steel Co., Limited.)

The tables for I beams and channels are calculated for all standard weights to which each pattern is rolled. The tables for deck-beams and angles are calculated for the minimum and maximum weights of the various shapes, while the properties of Z bars are given for thicknesses differing by 1/16 inch.

For tees, each shape can be rolled to one weight only.

Column 12 in the tables for I beams and channels, and column 9 for deck-beams, give coefficients by the help of which the safe, uniformly distributed load may be readily determined. To do this, divide the coefficient given by the span or distance between supports in feet. If the weight of the deck-beams is intermediate between the minimum and maximum weights given, add to the coefficient for the minimum weight the value given for one pound increase of weight multiplied by the number of pounds the section is heavier than the minimum.

If a section is to be selected (as will usually be the case), intended to carry a certain load for a length of span already determined on, ascertain the coefficient which this load and span will require, and refer to the table for a section having a coefficient of this value. The coefficient is obtained by multiplying the load, in pounds uniformly distributed, by the span length in feet.

In case the load is not uniformly distributed, but is concentrated at the middle of the span, multiply the load by 2, and then consider it as uniformly distributed. The deflection will be 8/10 of the deflection for the latter load.

For other cases of loading obtain the bending moment in ft.-lbs.; this multiplied by 8 will give the coefficient required.

If the loads are quiescent, the coefficients for a fibre stress of 16,000 lbs. per square inch for steel may be used; but if moving loads are to be provided for, a coefficient of 12,500 lbs. should be taken. Inasmuch as the effects of impact may be very considerable (the stresses produced in an unyielding inelastic material by a load suddenly applied being double those produced by the same load in a quiescent state), it will sometimes be advisable to use still smaller fibre stresses than those given in the tables. In such cases the coefficients may be determined by proportion. Thus, for a fibre stress of 8,000 lbs. per square inch the coefficient will equal the coefficient for 16,000 lbs. fibre stress, from the table, divided by 2.

The section moduli, column 11, are used to determine the fibre stress per square inch in a beam, or other shape, subjected to bending or transverse stresses, by simply dividing the bending moment expressed in inch-pounds by the section modulus.

In the case of T shapes with the neutral axis parallel to the flange, there will be two section moduli, and the smaller is given. The fibre stress calculated from it will, therefore, give the larger of the two stresses in the extreme fibres, since these stresses are equal to the bending moment divided by the section modulus of the section.

For Z bars the coefficients (C) may be applied for cases where the bars are subjected to transverse loading, as in the case of roof-purlins.

For angles, there will be two section moduli for each position of the neutral axis, since the distance between the neutral axis and the extreme fibres has a different value on one side of the axis from what it has on the other. The section modulus given in the table is the smaller of these two values.

Column 12 in the table of the properties of standard channels, giving the distance of the center of gravity of channel from the outside of web, is used to obtain the radius of gyration for columns or struts consisting of two channels latticed, for the case of the neutral axis passing through the centre of the cross-section parallel to the webs of the channels. This radius of gyration is equal to the distance between the centre of gravity of the channel and the centre of the section, i.e., neglecting the moments of inertia of the channels around their own axes, thereby introducing a slight error on the side of safety.

(For much other important information concerning rolled structural shapes, see the "Pocket Companion" of The Carnegie Steel Co., Limited, Pittsburg, Pa., price \$2.)

For any other load than 100 lbs. per square foot, divide the spacing given by the ratio the given load per square foot bears to 100. Thus for a load of 150 lbs. per square foot divide by 1.5. Maximum fibre stress, 16,000 lbs. per square inch. Only figures above the cross-lines should be used for plastered ceilings, so that the deflection will not cause cracking of the plaster.

*L* = safe load in lbs., uniformly distributed; *l* = span in feet; *M* = moment of forces in ft.-lbs.; *C* = coefficient given above.

$$L = \frac{C}{l}; \quad M = \frac{C}{8}; \quad C = Ll = 8M = \frac{8fS}{12}; \quad f = \text{fibre stress.}$$

Dimensions of lightest weight bars of each size: Z1, Z2, and Z3, depth of web 6 in., width of flange  $3\frac{1}{2}$  in., thickness of metal respectively  $\frac{3}{8}$ ,  $\frac{9}{16}$ , and  $\frac{3}{4}$  in.; Z4, Z5, Z6,  $5 \times 3\frac{1}{4} \times 5/16$ ,  $\frac{1}{2}$ , and  $11/16$  in.; Z7, Z8, Z9,  $4 \times 3\frac{1}{16} \times \frac{1}{4}$ ,  $7/16$ , and  $5/8$  in.; Z10, Z11, Z12,  $3 \times 2\frac{11}{16} \times \frac{1}{4}$ ,  $\frac{3}{8}$ , and  $\frac{1}{2}$  in. Each dimension is increased  $1/16$  in. in the next heavier weight.

**FLOORING MATERIAL.**

For fire-proof flooring, the space between the floor-beams may be spanned with brick arches, or with hollow brick made especially for the purpose, the latter being much lighter than ordinary brick.

Arches 4 inches deep of solid brick weigh about 70 lbs. per square foot, including the concrete levelling material, and substantial floors are thus made up to 6 feet span of arch, or much greater span if the skew backs at the springing of the arch are made deeper, the rise of the arch being preferably not less than 1/10 of the span. Hollow brick for floors are usually in depth about 1/8 of the span, and are used up to, and even exceeding, spans of 10 feet. The weight of the latter material will vary from 20 lbs. per square foot for 3-foot spans up to 60 lbs. per square foot for spans of 10 feet. Full particulars of this construction are given by the manufacturers. For supporting brick floors the beams should be securely tied with rods to resist the lateral pressure.

In the following cases the loads, in addition to the weight of the floor itself, may be assumed as:

For street bridges for general public traffic.....	80 lbs. per sq. ft.
For floors of dwellings .....	40 lbs. " "
For churches, theatres, and ball-rooms.....	80 lbs. " "
For hay-lofts ... ..	80 lbs. " "
For storage of grain.....	100 lbs. " "
For warehouses and general merchandise.....	250 lbs. " "
For factories.....	200 to 400 lbs. " "
For snow thirty inches deep.....	16 lbs. " "
For maximum pressure of wind .....	50 lbs. " "
For brick walls.....	112 lbs. per cu. ft.
For masonry walls.....	116-144 lbs. " "

Roofs, allowing thirty pounds per square foot for wind and snow:

For corrugated iron laid directly on the purlins...	37 lbs. per sq. ft.
For corrugated iron laid on boards.....	40 lbs. " "
For slate nailed to laths.....	43 lbs. " "
For slate nailed on boards.....	46 lbs. " "

If plastered below the rafters, the weight will be about ten pounds per square foot additional.

**TIE-RODS FOR BEAMS SUPPORTING BRICK ARCHES.**

The horizontal thrust of brick arches is as follows:

$$\frac{1.5WS^2}{R} = \text{pressure in pounds. per lineal foot of arch:}$$

$W$  = load in pounds. per square foot;

$S$  = span of arch in feet;

$R$  = rise in inches.

Place the tie-rods as low through the webs of the beams as possible and spaced so that the pressure of arches as obtained above will not produce a greater stress than 15,000 lbs. per square inch of the least section of the bolt,

**TORSIONAL STRENGTH.**

Let a horizontal shaft of diameter =  $d$  be fixed at one end, and at the other or free end, at a distance =  $l$  from the fixed end, let there be fixed a horizontal lever arm with a weight =  $P$  acting at a distance =  $a$  from the axis of the shaft so as to twist it; then  $Pa$  = moment of the applied force.

Resisting moment = twisting moment =  $\frac{SJ}{c}$ , in which  $S$  = unit shearing resistance,  $J$  = polar moment of inertia of the section with respect to the axis, and  $c$  = distance of the most remote fibre from the axis, in a cross-section. For a circle with diameter  $d$ ,

$$J = \frac{\pi d^4}{32}; \quad c = \frac{1}{2}d;$$

$$P\theta = \frac{SJ}{c} = \frac{\pi d^3 S}{16} = \frac{d^3 S}{5.1} = .1963d^3 S; \quad d = \sqrt[3]{\frac{5.1Pa}{S}}$$

For hollow shafts of external diameter  $d$  and internal diameter  $d_1$ ,

$$Pa = .1963 \frac{d^4 - d_1^4}{d} S; \quad d = \sqrt[3]{\frac{5.1Pa}{\left(1 - \frac{d_1^4}{d^4}\right) S}}$$

For a square whose side =  $d$ ,

$$J = \frac{d^4}{6}; \quad c = d \sqrt{1/2}; \quad \frac{SJ}{c} = Pa = \frac{d^3 S}{4.2426} = 0.236 d^3 S.$$

For a rectangle whose sides are  $b$  and  $d$ ,

$$J = \frac{bd^3}{12} + \frac{b^3d}{12}; \quad c = \frac{1}{2} \sqrt{b^2 + d^2}; \quad \frac{SJ}{c} = Pa = \frac{(bd^3 + b^3d)S}{6 \sqrt{b^2 + d^2}}.$$

The above formulæ are based on the supposition that the shearing resistance at any point of the cross-section is proportional to its distance from the axis; but this is true only within the elastic limit. In materials capable of flow, while the particles near the axis are strained within the elastic limit those at some distance within the circumference may be strained nearly to the ultimate resistance, so that the total resistance is something greater than that calculated by the formulæ. (See Thurston, "Mats. of Eng.," Part II. p. 527.) Saint Venant finds for square shafts  $Pa = 0.208d^3S$  (Cotterill, "Applied Mechanics," pp. 348, 355). For working strength, however, the formulæ may be used, with  $S$  taken at the safe working unit resistance.

For a rectangle, sides  $b$  (longer) and  $d$  (shorter) and area  $A$ ,

$$Pa = \frac{SA^2}{3b + 1.8d}.$$

The ultimate torsional shearing resistance  $S$  is about the same as the direct shearing resistance, and may be taken at 20,000 to 25,000 lbs. per square inch for cast iron, 45,000 lbs. for wrought iron, and 50,000 to 150,000 lbs. for steel, according to its carbon and temper. Large factors of safety should be taken, especially when the direction of stress is reversed, as in reversing engines, and when the torsional stress is combined with other stresses, as is usual in shafting. (See "Shafting.")

**Elastic Resistance to Torsion.**—Let  $l$  = length of bar being twisted,  $d$  = diameter,  $P$  = force applied at the extremity of a lever arm of length =  $a$ ,  $Pa$  = twisting moment,  $G$  = torsional modulus of elasticity,  $\theta$  = angle through which the free end of the shaft is twisted, measured in arc of radius = 1.

For a cylindrical shaft

$$Pa = \frac{\pi \theta G d^4}{32l}; \quad \theta = \frac{32Pal}{\pi d^4 G}; \quad G = \frac{32Pal}{\theta \pi d^4}; \quad \frac{32}{\pi} = 10.186.$$

If  $\alpha$  = angle of torsion in degrees,

$$\theta = \frac{\alpha \pi}{180}; \quad \alpha = \frac{180 \theta}{\pi} = \frac{180 \times 32Pal}{\pi^2 d^4 G} = \frac{583.6Pal}{d^4 G}.$$

The value of  $G$  is given by different authorities as from  $1/8$  to  $2/5$  of  $E$ , the modulus of elasticity for tension.

### COMBINED STRESSES.

(From Merriman's "Strength of Materials.")

**Combined Tension and Flexure.**—Let  $A$  = the area of a bar subjected to both tension and flexure,  $P$  = tensile stress applied at the ends,  $P \div A$  = unit tensile stress,  $S$  = unit stress at the fibre on the tensile side most remote from the neutral axis, due to flexure alone, then maximum tensile unit stress =  $(P \div A) + S$ . A beam to resist combined tension and flexure should be designed so that  $(P \div A) + S$  shall not exceed the proper allowable working unit stress.

**Combined Compression and Flexure.**—If  $P \div A$  = unit stress due to compression alone, and  $S$  = unit compressive stress at fibre most remote from neutral axis, due to flexure alone, then maximum compressive unit stress =  $(P \div A) + S$ .

**Combined Tension (or Compression) and Shear.**—If ap-

plied tension (or compression) unit stress =  $p$ , applied shearing unit stress =  $v$ , then from the combined action of the two forces

$$\text{Max. } S = \pm \sqrt{v^2 + \frac{1}{4}p^2}, \quad \text{Maximum shearing unit stress;}$$

$$\text{Max. } t = \frac{1}{2}p + \sqrt{v^2 + \frac{1}{4}p^2}, \quad \text{Maximum tensile (or compressive) unit stress.}$$

**Combined Flexure and Torsion.**—If  $S$  = greatest unit stress due to flexure alone, and  $S_s$  = greatest torsional shearing unit stress due to torsion alone, then for the combined stresses

$$\text{Max. tension or compression unit stress } t = \frac{1}{2}S + \sqrt{S_s^2 + \frac{1}{4}S^2};$$

$$\text{Max. shear } s = \pm \sqrt{S_s^2 + \frac{1}{4}S^2}.$$

Formula for diameter of a round shaft subjected to transverse load while transmitting a given horse-power (see also Shafts of Engines):

$$d^3 = \frac{16M}{\pi t} + \frac{16}{t} \sqrt{\frac{M^2}{\pi^2} + \frac{402,500,000H^2}{n^2}},$$

where  $M$  = maximum bending moment of the transverse forces in pound-inches,  $H$  = horse-power transmitted,  $n$  = No. of revs. per minute, and  $t$  = the safe allowable tensile or compressive working strength of the material.

**Combined Compression and Torsion.**—For a vertical round shaft carrying a load and also transmitting a given horse-power, the resultant maximum compressive unit stress

$$t = \frac{4P}{\pi d^2} + \sqrt{321,000^2 \frac{H^2}{n^2 d^6} + \frac{16P^2}{\pi^2 d^4}},$$

in which  $P$  is the load. From this the diameter  $d$  may be found when  $t$  and the other data are given.

**Stress due to Temperature.**—Let  $l$  = length of a bar,  $A$  = its sectional area,  $c$  = coefficient of linear expansion for one degree,  $t$  = rise or fall in temperature in degrees,  $E$  = modulus of elasticity,  $\lambda$  the change of length due to the rise or fall  $t$ ; if the bar is free to expand or contract,  $\lambda = ctl$ .

If the bar is held so as to prevent its expansion or contraction the stress produced by the change of temperature =  $S = ActE$ . The following are average values of the coefficients of linear expansion for a change in temperature of one degree Fahrenheit:

- For brick and stone.... $a = 0.0000050$ ,
- For cast iron..... $a = 0.0000062$ ,
- For wrought iron..... $a = 0.0000067$ ,
- For steel..... $a = 0.0000065$ .

The stress due to temperature should be added to or subtracted from the stress caused by other external forces according as it acts to increase or to relieve the existing stress.

What stress will be caused in a steel bar 1 inch square in area by a change of temperature of 100° F. ?  $S = ActE = 1 \times .0000065 \times 100 \times 30,000,000 = 19,500$  lbs. Suppose the bar is under tension of 19,500 lbs. between rigid abutments before the change in temperature takes place, a cooling of 100° F. will double the tension, and a heating of 100° will reduce the tension to zero.

**STRENGTH OF FLAT PLATES.**

For a circular plate supported at the edge, uniformly loaded, according to Grashof,

$$f = \frac{5}{6} \frac{r^2}{t^2} p; \quad t = \sqrt{\frac{5r^2 p}{6f}}; \quad p = \frac{6ft^2}{5r^2}.$$

For a circular plate fixed at the edge, uniformly loaded,

$$f = \frac{2}{3} \frac{r^2}{t^2} p; \quad t = \sqrt{\frac{2}{3} \frac{r^2 p}{f}}; \quad p = \frac{3ft^2}{2r^2};$$

in which  $f$  denotes the working stress;  $r$ , the radius in inches;  $t$ , the thickness in inches; and  $p$ , the pressure in pounds per square inch.

For mathematical discussion, see Lanza, "Applied Mechanics," p. 900, etc. Lanza gives the following table, using a factor of safety of 8, with tensile strength of cast iron 20,000, of wrought iron 40,000, and of steel 80,000 :

	Supported.	Fixed.
Cast iron.....	$t = .0182570r \sqrt{p}$	$t = .0163300r \sqrt{p}$
Wrought iron.....	$t = .0117850r \sqrt{p}$	$t = .0105410r \sqrt{p}$
Steel.....	$t = .0091287r \sqrt{p}$	$t = .0081649r \sqrt{p}$

For a circular plate supported at the edge, and loaded with a concentrated load  $P$  applied at a circumference the radius of which is  $r_0$ :

$$f = \left( \frac{4}{3} \log \frac{r}{r_0} + 1 \right) \frac{P}{\pi t^2} = c \frac{P}{\pi t^2};$$

for  $\frac{r}{r_0} = 10 \quad 20 \quad 30 \quad 40 \quad 50;$   
 $c = 4.07 \quad 5.00 \quad 5.53 \quad 5.92 \quad 6.22;$   
 $t = \sqrt{\frac{cP}{\pi f}}; \quad P = \frac{\pi t^2 f}{c}.$

The above formulæ are deduced from theoretical considerations, and give thicknesses much greater than are generally used in steam-engine cylinder-heads. (See empirical formulæ under Dimensions of Parts of Engines.) The theoretical formulæ seem to be based on incorrect or incomplete hypotheses, but they err in the direction of safety.

**The Strength of Unstayed Flat Surfaces.**—Robert Wilson (*Eng'g*, Sept. 24, 1877) draws attention to the apparent discrepancy between the results of theoretical investigations and of actual experiments on the strength of unstayed flat surfaces of boiler-plate, such as the unstayed flat crowns of domes and of vertical boilers.

Rankine's "Civil Engineering" gives the following rules for the strength of a circular plate *supported* all round the edge, prefaced by the remark that "the formula is founded on a theory which is only approximately true, but which nevertheless may be considered to involve no error of practical importance."

$$M = \frac{Wb}{6\pi} = \frac{Pb^3}{24}.$$

Here

- $M$  = greatest bending moment ;
- $W$  = total load uniformly distributed =  $\frac{Pb^2\pi}{4}$ ;
- $b$  = diameter of plate in inches ;
- $P$  = bursting pressure in pounds per square inch.

Calling  $t$  the thickness in inches, for a plate *supported* round the edges,

$$M = \frac{1}{6} 42,000bt^2; \quad \therefore \frac{Pb^2}{24} = 7000t^2.$$

For a plate *fixed* round the edges,

$$\frac{2}{3} \frac{Pb^2}{24} = 7000t^2; \quad \text{whence } P = \frac{t^2 \times 63,000}{r^2},$$

where  $r$  = radius of the plate.

Dr. Grashof gives a formula from which we have the following rule:

$$P = \frac{t^2 \times 72,000}{r^2}.$$

This formula of Grashof's has been adopted by Professor Unwin in his "Elements of Machine Design." These formulæ by Rankine and Grashof may be regarded as being practically the same.

On trying to make the rules given by these authorities agree with the results of his experience of the strength of unstayed flat ends of cylindrical boilers and domes that had given way after long use, Mr. Wilson was led to believe that the above rules give the breaking strength much lower than it

actually is. He describes a number of experiments made by Mr. Nichols of Kirkstall, which gave results varying widely from each other, as the method of supporting the edges of the plate was varied, and also varying widely from the calculated bursting pressures, the actual results being in all cases very much the higher. Some conclusions drawn from these results are:

1. Although the bursting pressure has been found to be so high, boiler-makers must be warned against attaching any importance to this, since the plates deflected almost as soon as any pressure was put upon them and sprang back again on the pressure being taken off. This springing of the plate in the course of time inevitably results in grooving or channelling, which, especially when aided by the action of the corrosive acids in the water or steam, will in time reduce the thickness of the plate, and bring about the destruction of an unstayed surface at a very low pressure.

2. Since flat plates commence to deflect at very low pressures, they should never be used without stays; but it is better to dish the plates when they are not stayed by flues, tubes, etc.

3. Against the commonly accepted opinion that the limit of elasticity should never be reached in testing a boiler or other structure, these experiments show that an exception should be made in the case of an unstayed flat end-plate of a boiler, which will be safer when it has assumed a permanent set that will prevent its becoming grooved by the continual variation of pressure in working. The hydraulic pressure in this case simply does what should have been done before the plate was fixed, that is, dishes it.

4. These experiments appear to show that the mode of attaching by flange or by an inside or outside angle-iron exerts an important influence on the manner in which the plate is strained by the pressure.

When the plate is secured to an angle-iron, the stretching under pressure is, to a certain extent, concentrated at the line of rivet-holes, and the plate partakes rather of a beam supported than fixed round the edge. Instead of the strength increasing as the square of the thickness, when the plate is attached by an angle-iron, it is probable that the strength does not increase even directly as the thickness, since the plate gives way simply by stretching at the rivet-holes, and the thicker the plate, the less uniformly is the strain borne by the different layers of which the plate may be considered to be made up. When the plate is flanged, the flange becomes compressed by the pressure against the body of the plate, and near the rim, as shown by the contrary flexure, the inside of the plate is stretched more than the outside, and it may be by a kind of shearing action that the plate gives way along the line where the crushing and stretching meet.

5. These tests appear to show that the rules deduced from the theoretical investigations of Lamé, Rankine, and Grashof are not confirmed by experiment, and are therefore not trustworthy.

The rules of Lamé, etc., apply only within the elastic limit. (*Eng'g*, Dec. 13, 1895.)

**Unbraced Wrought-iron Heads of Boilers, etc.** (*The Locomotive*, Feb. 1890).—Few experiments have been made on the strength of flat heads, and our knowledge of them comes largely from theory. Experiments have been made on small plates 1-16 of an inch thick, yet the data so obtained cannot be considered satisfactory when we consider the far thicker heads that are used in practice, although the results agreed well with Rankine's formula. Mr. Nichols has made experiments on larger heads, and from them he has deduced the following rule: "To find the proper thickness for a flat unstayed head, multiply the area of the head by the pressure per square inch that it is to bear safely, and multiply this by the desired factor of safety (say 8); then divide the product by ten times the tensile strength of the material used for the head." His rule for finding the bursting pressure when the dimensions of the head are given is: "Multiply the thickness of the end-plate in inches by ten times the tensile strength of the material used, and divide the product by the area of the head in inches."

In Mr. Nichols's experiments the average tensile strength of the iron used for the heads was 44,800 pounds. The results he obtained are given below, with the calculated pressure, by his rule, for comparison.

1. An unstayed flat boiler-head is  $34\frac{1}{2}$  inches in diameter and 9-16 inch thick. What is its bursting pressure? The area of a circle  $34\frac{1}{2}$  inches in diameter is 935 square inches; then  $9-16 \times 44,800 \times 10 = 252,000$ , and  $252,000 \div 935 = 270$  pounds, the calculated bursting pressure. The head actually burst at 280 pounds.

2. Head  $34\frac{1}{2}$  inches in diameter and  $\frac{3}{8}$  inch thick. The area = 935 square inches; then,  $\frac{3}{8} \times 44,800 \times 10 = 168,000$ , and  $168,000 \div 935 = 180$  pounds, calculated bursting pressure. This head actually burst at 200 pounds.

3. Head  $26\frac{1}{4}$  inches in diameter, and  $\frac{3}{8}$  inch thick. The area 541 square inches. Then,  $\frac{3}{8} \times 44,800 \times 10 = 168,000$ , and  $168,000 \div 541 = 311$  pounds. This head burst at 370 pounds.

4. Head  $28\frac{1}{2}$  inches in diameter and  $\frac{3}{8}$  inch thick. The area = 638 square inches; then,  $\frac{3}{8} \times 44,800 \times 10 = 168,000$ , and  $168,000 \div 638 = 263$  pounds. The actual bursting pressure was 300 pounds.

In the third experiment, the amount the plate bulged under different pressures was as follows :

At pounds per sq. in....	10	20	40	80	120	140	170	200
Plate bulged.....	$1/32$	$1/16$	$1/8$	$1/4$	$3/8$	$1/2$	$5/8$	$3/4$

The pressure was now reduced to zero, " and the end sprang back 3-16 inch, leaving it with a permanent set of 9-16 inch. The pressure of 200 lbs. was again applied on 36 separate occasions during an interval of five days, the bulging and permanent set being noted on each occasion, but without any appreciable difference from that noted above.

The experiments described were confined to plates not widely different in their dimensions, so that Mr. Nichols's rule cannot be relied upon for heads that depart much from the proportions given in the examples.

**Thickness of Flat Cast-iron Plates to resist Bursting Pressures.**—Capt. John Ericsson (Church's Life of Ericsson) gave the following rules: The proper thickness of a square cast-iron plate will be obtained by the following: Multiply the side in feet (or decimals of a foot) by  $\frac{1}{4}$  of the pressure in pounds and divide by 850 times the side in inches; the quotient is the square of the thickness in inches.

For a circular plate, multiply 11-14 of the diameter in feet by  $\frac{1}{4}$  of the pressure on the plate in pounds. Divide by 850 times 11-14 of the diameter in inches. [Extract the square root.]

Prof. Wm. Harkness, *Eng'g News*, Sept. 5, 1895, shows that these rules can be put in a more convenient form, thus:

For square plates  $T = 0.00495S \sqrt{p}$ ,  
and

For circular plates  $T = 0.00439D \sqrt{p}$ ,

where  $T$  = thickness of plate,  $S$  = side of the square,  $D$  = diameter of the circle, and  $p$  = pressure in lbs. per sq. in. Professor Harkness, however, doubts the value of the rules, and says that no satisfactory theoretical solution has yet been obtained.

**Strength of Stayed Surfaces.**—A flat plate of thickness  $t$  is supported uniformly by stays whose distance from centre to centre is  $a$ , uniform load  $p$  lbs. per square inch. Each stay supports  $pa^2$  lbs. The greatest stress on the plate is

$$f = \frac{2}{9} \frac{a^2}{t^2} p. \text{ (Unwin).}$$

**SPHERICAL SHELLS AND DOMED BOILER-HEADS.**

**To find the Thickness of a Spherical Shell to resist a given Pressure.**—Let  $d$  = diameter in inches, and  $p$  the internal pressure per square inch. The total pressure which tends to produce rupture around the great circle will be  $\frac{1}{4}\pi d^2 p$ . Let  $S$  = safe tensile stress per square inch, and  $t$  the thickness of metal in inches; then the resistance to the pressure will be  $\pi dtS$ . Since the resistance must be equal to the pressure.

$$\frac{1}{4}\pi d^2 p = \pi dtS. \text{ Whence } t = \frac{pd}{4S}.$$

The same rule is used for finding the thickness of a hemispherical head to a cylinder, as of a cylindrical boiler.

**Thickness of a Domed Head of a boiler.**—If  $S$  = safe tensile stress per square inch,  $d$  = diameter of the shell in inches, and  $t$  = thickness of the shell,  $t = pd \div 2S$ ; but the thickness of a hemispherical head of the same diameter is  $t = pd \div 4S$ . Hence if we make the radius of curvature of a domed head equal to the diameter of the boiler, we shall have  $t = \frac{2pd}{4S} = \frac{pd}{2S}$ , or the thickness of such a domed head will be equal to the thickness of the shell.

**Stresses in Steel Plating due to Water-pressure**, as in plating of vessels and bulkheads (*Engineering*, May 22, 1891, page 629).

Mr. J. A. Yates has made calculations of the stresses to which steel plates are subjected by external water-pressure, and arrives at the following conclusions :

Assume  $2a$  inches to be the distance between the frames or other rigid supports, and let  $d$  represent the depth in feet, below the surface of the water, of the plate under consideration,  $t$  = thickness of plate in inches,  $D$  the deflection from a straight line under pressure in inches, and  $P$  = stress per square inch of section.

For outer bottom and ballast-tank plating,  $a = 420 \frac{t}{d}$ ,  $D$  should not be greater than  $.05 \frac{2a}{12}$ , and  $\frac{P}{2}$  not greater than 2 to 3 tons ; while for bulkheads, etc.,  $a = 2352 \frac{t}{d}$ ,  $D$  should not be greater than  $.1 \frac{2a}{12}$ , and  $\frac{P}{2}$  not greater than 7 tons. To illustrate the application of these formulæ the following cases have been taken :

For Outer Bottom, etc.			For Bulkheads, etc.		
Thick-ness of Plating.	Depth below Water.	Spacing of Frames should not exceed	Thick-ness of Plating	Depth of Water.	Maximum Spac- ing of Rigid Stiffeners.
in.	ft.	in.	in.	ft.	ft. in.
$\frac{1}{8}$	20	About 21	$\frac{1}{2}$	20	9 10
$\frac{1}{8}$	10	“ 42	$\frac{3}{8}$	20	7 4
$\frac{3}{8}$	18	“ 18	$\frac{3}{8}$	10	14 8
$\frac{3}{8}$	9	“ 36	$\frac{1}{4}$	20	4 10
$\frac{1}{4}$	10	“ 20	$\frac{1}{4}$	10	9 8
$\frac{1}{4}$	5	“ 40	$\frac{1}{8}$	10	4 10

It would appear that the course which should be followed in stiffening bulkheads is to fit substantially rigid stiffening frames at comparatively wide intervals, and only work such light angles between as are necessary for making a fair job of the bulkhead.

**THICK HOLLOW CYLINDERS UNDER TENSION.**

Burr, “Elasticity and Resistance of Materials,” p. 36, gives

$$t = r \left\{ \left( \frac{h + p}{h - p} \right)^{\frac{1}{2}} - 1 \right\} .$$

$t$  = thickness ;  $r$  = interior radius ;  
 $h$  = maximum allowable hoop tension at the interior of the cylinder ;  
 $p$  = intensity of interior pressure.

Merriman gives

$s$  = unit stress at inner edge of the annulus ;  
 $r$  = interior radius ;  $t$  = thickness ;  
 $l$  = length.

The total stress over the area  $2tl = 2sl \frac{rt}{r+t} \dots \dots \dots (1)$

The total interior pressure which tends to rupture the cylinder is  $2rl \times p$ . If  $p$  be the unit pressure, then  $p = \frac{st}{r+t}$ , from which one of the quantities  $s$ ,  $p$ ,  $r$ , or  $t$  can be found when the other three are given.

$$s = \frac{p(r+t)}{t}; \quad r = \frac{(s-p)t}{p}; \quad t = \frac{rp}{s-p}.$$

In eq. (1), if  $t$  be neglected in comparison with  $r$ , it reduces to  $2slt$ , which is the same as the formula for thin cylinders. If  $t = r$ , it becomes  $slt$ , or only half the resistance of the thin cylinder.

The formulæ given by Burr and by Merriman are quite different, as will be seen by the following example: Let maximum unit stress at the inner edge of the annulus = 8000 lbs. per square inch, radius of cylinder = 4 inches, interior pressure = 4000 lbs. per square inch. Required the thickness.

$$\text{By Burr, } t = 4 \left\{ \left( \frac{8000 + 4000}{8000 - 4000} \right)^{\frac{1}{2}} - 1 \right\} = 4(\sqrt{3} - 1) = 2.928 \text{ inches.}$$

$$\text{By Merriman, } t = \frac{4 \times 4000}{8000 - 4000} = 4 \text{ inches.}$$

**Limit to Useful Thickness of Hollow Cylinders** (*Eng'g*, Jan. 4, 1884).—Professor Barlow lays down the law of the resisting powers of thick cylinders as follows:

“In a homogeneous cylinder, if the metal is incompressible, the tension on every concentric layer, caused by an internal pressure, varies inversely as the square of its distance from the centre.”

Suppose a twelve-inch gun to have walls 15 inches thick.

$$\frac{\text{Pressure on exterior}}{\text{Pressure on interior}} = \frac{6^2}{21^2} = 1 : 12.25.$$

So that if the stress on the interior is  $12\frac{1}{4}$  tons per square inch, the stress on the exterior is only 1 ton.

Let  $s$  = the stress on the inner layer, and  $s_1$  that at a distance  $x$  from the axis;  $r$  = internal radius,  $R$  = external radius.

$$s_1 : s :: r^2 : x^2, \text{ or } s_1 = s \frac{r^2}{x^2}.$$

The whole stress on a section 1 inch long, extending from the interior to the exterior surface, is  $S = sr \times \frac{R - r}{R}$ .

In a 12-inch gun, let  $s = 40$  tons,  $r = 6$  in.,  $R = 21$  in.

$$S = 40 \times 6 \times \frac{21 - 6}{21} = 172 \text{ tons.}$$

Suppose now we go on adding metal to the gun outside: then  $R$  will become so large compared with  $r$ , that  $R - r$  will approach the value  $R$ , so that the fraction  $\frac{R - r}{R}$  becomes nearly unity.

Hence for an infinitely thick cylinder the useful strength could never exceed  $Sr$  (in this case 240 tons).

Barlow's formula agrees with the one given by Merriman.

Another statement of the gun problem is as follows: Using the formula

$$p = \frac{st}{r + t},$$

$s = 40$  tons,  $t = 15$  in.,  $r = 6$  in.,  $p = \frac{40 \times 15}{21} = 28\frac{4}{7}$  tons per sq. in.,  $28\frac{4}{7} \times$  radius = 172 tons, the pressure to be resisted by a section 1 inch long of the thickness of the gun on one side. Suppose thickness were doubled, making  $t = 30$  in.:  $p = \frac{40 \times 30}{36} = 33\frac{1}{3}$  tons, or an increase of only 16 per cent.

For short cast-iron cylinders, such as are used in hydraulic presses, it is doubtful if the above formulæ hold true, since the strength of the cylindrical portion is reinforced by the end. In that case the bursting strength would be higher than that calculated by the formula. A rule used in practice for such presses is to make the thickness =  $1/10$  of the inner circumference, for pressures of 3000 to 4000 lbs. per square inch. The latter pressure would bring a stress upon the inner layer of 10,350 lbs. per square inch, as calculated by the formula; which would necessitate the use of the best charcoal-iron to make the press reasonably safe.

**THIN CYLINDERS UNDER TENSION.**

Let  $p$  = safe working pressure in lbs. per sq. in.;  
 $d$  = diameter in inches;  
 $T$  = tensile strength of the material, lbs. per sq. in.;  
 $t$  = thickness in inches;  
 $f$  = factor of safety;  
 $c$  = ratio of strength of riveted joint to strength of solid plate.

$$fpd = 2Ttc; \quad p = \frac{2Ttc}{df}; \quad t = \frac{fpd}{2Tc}.$$

If  $T = 50000$ ,  $f = 5$ , and  $c = 0.7$ ; then

$$p = \frac{14000t}{d}; \quad t = \frac{dp}{14000}.$$

The above represents the strength resisting rupture along a longitudinal seam. For resistance to rupture in a circumferential seam, due to pressure on the ends of the cylinder, we have  $\frac{p\pi d^2}{4} = \frac{Tt\pi dc}{f}$ ;

$$\text{whence } p = \frac{4Ttc}{df}.$$

Or the strength to resist rupture around a circumference is twice as great as that to resist rupture longitudinally; hence boilers are commonly single-riveted in the circumferential seams and double-riveted in the longitudinal seams.

**HOLLOW COPPER BALLS.**

Hollow copper balls are used as floats in boilers or tanks, to control feed and discharge valves, and regulate the water-level.

They are spun up in halves from sheet copper, and a rib is formed on one half. Into this rib the other half fits, and the two are then soldered or brazed together. In order to facilitate the brazing, a hole is left on one side of the ball, to allow air to pass freely in or out; and this hole is made use of afterwards to secure the float to its stem. The original thickness of the metal may be anything up to about 1-16 of an inch, if the spinning is done on a hand lathe, though thicker metal may be used when special machinery is provided for forming it. In the process of spinning, the metal is thinned down in places by stretching; but the thinnest place is neither at the equator of the ball (i.e., along the rib) nor at the poles. The thinnest points lie along two circles, passing around the ball parallel to the rib, one on each side of it, from a third to a half of the way to the poles. Along these lines the thickness may be 10, 15, or 20 per cent less than elsewhere, the reduction depending somewhat on the skill of the workman.

The *Locomotive* for October, 1891, gives two empirical rules for determining the thickness of a copper ball which is to work under an external pressure, as follows:

1. Thickness =  $\frac{\text{diameter in inches} \times \text{pressure in pounds per sq. in.}}{16,000}$ .
2. Thickness =  $\frac{\text{diameter} \times \sqrt{\text{pressure}}}{1240}$ .

These rules give the same result for a pressure of 166 lbs. only. Example: Required the thickness of a 5-inch copper ball to sustain

Pressures of.....	50	100	150	166	200	250 lbs. per sq. in.
Answer by first rule...	.0156	.0312	.0469	.0519	.0625	.0781 inch.
Answer by second rule	.0285	.0403	.0494	.0518	.0570	.0637 "

**HOLDING-POWER OF NAILS, SPIKES, AND SCREWS.**

(A. W. Wright, Western Society of Engineers, 1881.)

**Spikes.**—Spikes driven into dry cedar (cut 18 months):

Size of spikes.....	5 × ¼ in. sq.	6 × ¼	6 × ½	5 × ¾
Length driven in.....	4¼ in.	5 in.	5 in.	4¼ in.
Pounds resistance to drawing. Av'ge, lbs.	857	821	1691	1202
From 6 to 9 tests each.....	{ Max. " 1159	923	2129	1556
	{ Min. " 766	766	1120	687

A. M. Wellington found the force required to draw spikes  $9/16 \times 9/16$  in., driven  $4\frac{1}{4}$  inches into seasoned oak, to be 4281 lbs.; same spikes, etc., in unseasoned oak, 6523 lbs.

“Professor W. R. Johnson found that a plain spike  $3/8$  inch square driven  $3\frac{3}{8}$  inches into seasoned Jersey yellow pine or unseasoned chestnut required about 2000 lbs. force to extract it; from seasoned white oak about 4000 and from well-seasoned locust 6000 lbs.”

Experiments in Germany, by Funk, give from 2465 to 3940 lbs. (mean of many experiments about 3000 lbs.) as the force necessary to extract a plain  $1/2$ -inch square iron spike 6 inches long, wedge-pointed for one inch and driven  $4\frac{1}{2}$  inches into white or yellow pine. When driven 5 inches the force required was about  $1/10$  part greater. Similar spikes  $9/16$  inches square, 7 inches long, driven 6 inches deep, required from 3700 to 6745 lbs. to extract them from pine; the mean of the results being 4873 lbs. In all cases about twice as much force was required to extract them from oak. The spikes were all driven across the grain of the wood. When driven with the grain, spikes or nails do not hold with more than half as much force.

Boards of oak or pine nailed together by from 4 to 16 tenpenny common cut nails and then pulled apart in a direction lengthwise of the boards, and across the nails, tending to break the latter in two by a shearing action, averaged about 300 to 400 lbs. per nail to separate them, as the result of many trials.

**Resistance of Drift-bolts in Timber.**—Tests made by Rust and Coolidge, in 1878.

								Pounds	
1st Test.	1 in. square	iron	drove	30 in.	in	white	pine,	15/16-in. hole.....	26,400

**Force required to draw Wood Screws out of Dry Wood.**

—Tests made by Mr. Bevan. The screws were about two inches in length, .22 diameter at the exterior of the threads, .15 diameter at the bottom, the depth of the worm or thread being .035 and the number of threads in one inch equal 12. They were passed through pieces of wood half an inch in thickness and drawn out by the weights stated: Beech, 460 lbs.; ash, 790 lbs.; oak, 760 lbs.; mahogany, 770 lbs.; elm, 665 lbs.; sycamore, 830 lbs.

**Tests of Lag-screws in Various Woods** were made by A. J. Cox, University of Iowa, 1891:

Kind of Wood.	Size Screw.	Size Hole bored.	Length in Tie.	Max. Resist. lbs.	No. Tests.
Seasoned white oak.....	$5/8$ in.	$1/2$ in.	$4\frac{1}{2}$ in.	8037	3
“ “ “.....	$9/16$ “	$7/16$ “	3 “	6480	1
“ “ “.....	$1/2$ “	$3/8$ “	$4\frac{1}{2}$ “	8780	2
Yellow-pine stick... ..	$5/8$ “	$1/2$ “	4 “	3800	2
White cedar, unseasoned.....	$5/8$ “	$1/2$ “	4 “	3405	2

In figuring area for lag-screws, the surface of a cylinder whose diameter is equal to that of the screw was taken. The length of the screw part in each case was 4 inches.—*Engineering News*, 1891.

**Cut versus Wire Nails.**—Experiments were made at the Watertown Arsenal in 1893 on the comparative direct tensile adhesion, in pine and spruce, of cut and wire nails. The results are stated by Prof. W. H. Burr as follows:

There were 58 series of tests, ten pairs of nails (a cut and a wire nail in each) being used, making a total of 1160 nails drawn. The tests were made in spruce wood in most instances, but some extra ones were made in white pine, with "box nails." The nails were of all sizes, varying from 1 1/8 inches to 6 inches in length. In every case the cut nails showed the superior holding strength by a large percentage. In spruce, in nine different sizes of nails, both standard and light weight, the ratio of tenacity of cut to wire nail was about 3 to 2, or, as he terms it, "a superiority of 47.45% of the former." With the "finishing" nails the ratio was roughly 3.5 to 2; superiority 72%. With box nails (1 1/4 to 4 inches long) the ratio was roughly 3 to 2; superiority 51%. The mean superiority in spruce wood was 61%. In white pine, cut nails, driven with taper along the grain, showed a superiority of 100%, and with taper across the grain of 135%. Also when the nails were driven in the end of the stick, i.e., along the grain, the superiority of cut nails was 100%, or the ratio of cut to wire was 2 to 1. The total of the results showed the ratio of tenacity to be about 3.2 to 2 for the harder wood, and about 2 to 1 for the softer, and for the whole taken together the ratio was 3.5 to 2. We are led to conclude that under these circumstances the cut nail is superior to the wire nail in direct tensile holding-power by 72.74%.

**Nail-holding Power of Various Woods.**

(Watertown Experiments.)

Tests made at the University of Illinois gave the resistance of a 1-in. round rod in a 15/16-inch hole perpendicular to the grain, as 6000 lbs. per lin. ft. in pine and 15,600 lbs. in oak. Experiments made at the East River Bridge gave resistances of 12,000 and 15,000 lbs. per lin. ft. for a 1-in. round rod in holes 15/16-in. and 14/16-in. diameter, respectively, in Georgia pine.

**Holding-power of Bolts in White Pine.**

(*Eng'g News*, September 26, 1891.)

	Round.	Square.
	Lbs.	Lbs.
Average of all plain 1-in. bolts.....	8224	8200

When it is known what load is to be put upon a bolt, and the judgment of the engineer has determined what stress is safe to put upon the iron, look down in the proper column of said stress until the required load is found. The area at the bottom of the thread will give the equivalent area of a flat bar to that of the bolt.

**Effect of Initial Strain in Bolts.**—Suppose that bolts are used to connect two parts of a machine and that they are screwed up tightly before the effective load comes on the connected parts. Let  $P_1$  = the initial tension on a bolt due to screwing up, and  $P_2$  = the load afterwards added. The greatest load may vary but little from  $P_1$  or  $P_2$ , according as the former or the latter is greater, or it may approach the value  $P_1 + P_2$ , depending upon the relative rigidity of the bolts and of the parts connected. Where rigid flanges are bolted together, metal to metal, it is probable that the extension of the bolts with any additional tension relieves the initial tension, and that the total tension is  $P_1$  or  $P_2$ , but in cases where elastic packing, as india rubber, is interposed, the extension of the bolts may very little affect the initial tension, and the total strain may be nearly  $P_1 + P_2$ . Since the latter assumption is more unfavorable to the resistance of the bolt, this contingency should usually be provided for. (See Unwin, "Elements of Machine Design" for demonstration.)

**STAND-PIPES AND THEIR DESIGN.**

(Freeman C. Coffin, New England Water Works Assoc., *Eng. News*, March 16, 1893.) See also papers by A. H. Howland, *Eng. Club of Phil.* 1887; B. F. Stephens, *Amer. Water Works Assoc.*, *Eng. News*, Oct. 6 and 13, 1888; W. Kiersted, *Rensselaer Soc. of Civil Eng.*, *Eng'g Record*, April 25 and May 2, 1891, and W. D. Pence, *Eng. News*, April and May, 1894.

The question of diameter is almost entirely independent of that of height. The efficient capacity must be measured by the length from the high-water line to a point below which it is undesirable to draw the water on account of loss of pressure for fire-supply, whether that point is the actual bottom of the stand-pipe or above it. This allowable fluctuation ought not to exceed 50 ft., in most cases. This makes the diameter dependent upon two condi-

tions, the first of which is the amount of the consumption during the ordinary interval between the stopping and starting of the pumps. This should never draw the water below a point that will give a good fire stream and leave a margin for still further draught for fires. The second condition is the maximum number of fire streams and their size which it is considered necessary to provide for, and the maximum length of time which they are liable to have to run before the pumps can be relied upon to reinforce them.

Another reason for making the diameter large is to provide for stability against wind-pressure when empty.

The following table gives the height of stand-pipes beyond which they are not safe against wind-pressures of 40 and 50 lbs. per square foot. The area of surface taken is the height multiplied by one half the diameter.

**Heights of Stand-pipe that will Resist Wind-pressure by its Weight alone, when Empty.**

Diameter, feet.	Wind, 40 lbs. per sq. ft.	Wind, 50 lbs. per sq. ft.
20.....	45	35
25.....	70	55
30.....	150	80
35.....	...	160

To have the above degree of stability the stand-pipes must be designed with the outside angle-iron at the bottom connection.

Any form of anchorage that depends upon connections with the side plates near the bottom is unsafe. By suitable guys the wind-pressure is resisted by tension in the guys, and the stand-pipe is relieved from wind strains that tend to overthrow it. The guys should be attached to a band of angle or other shaped iron that completely encircles the tank, and rests upon some sort of bracket or projection, and not be riveted to the tank. They should be anchored at a distance from the base equal to the height of the point at which they are attached, if possible.

The best plan is to build the stand-pipe of such diameter that it will resist the wind by its own stability.

**Thickness of the Side Plates.**

The pressure on the sides is outward, and due alone to the weight of the water, or pressure per square inch, and increases in direct ratio to the height, and also to the diameter. The strain upon a section 1 inch in height at any point is the total strain at that point divided by two—for each side is supposed to bear the strain equally. The total pressure at any point is equal to the diameter in inches, multiplied by the pressure per square inch, due to the height at that point. It may be expressed as follows:

- $H$  = height in feet, and  $f$  = factor of safety;
- $d$  = diameter in inches;
- $p$  = pressure in lbs. per square inch;
- $.434 = p$  for 1 ft. in height;
- $s$  = tensile strength of material per square inch;
- $T$  = thickness of plate.

Then the total strain on each side per vertical inch

$$= \frac{.434Hd}{2} = \frac{pd}{2}; \quad T = \frac{.434Hdf}{2s} = \frac{pdf}{2s}.$$

Mr. Coffin takes  $f = 5$ , not counting reduction of strength of joint, equivalent to an actual factor of safety of 3 if the strength of the riveted joint is taken as 60 per cent of that of the plate.

The amount of the wind strain per square inch of metal at any joint can be found by the following formula, in which

- $H$  = height of stand-pipe in feet above joint;
- $T$  = thickness of plate in inches;
- $p$  = wind-pressure per square foot;
- $W$  = wind-pressure per foot in height above joint;
- $W = Dp$  where  $D$  is the diameter in feet;
- $m$  = average leverage or movement about neutral axis or central points in the circumference; or,
- $m = \text{sine of } 45^\circ, \text{ or } .707 \text{ times the radius in feet.}$

Then the strain per square inch of plate

$$\frac{(Hw)\frac{H}{2}}{\text{circ. in ft.} \times mT}$$

Mr. Coffin gives a number of diagrams useful in the design of stand-pipes, together with a number of instances of failures, with discussion of their probable causes.

Mr. Kiersted's paper contains the following: Among the most prominent strains a stand-pipe has to bear are: that due to the static pressure of the water, that due to the overturning effect of the wind on an empty stand-pipe, and that due to the collapsing effect, on the upper rings, of violent wind storms.

For the thickness of metal to withstand safely the static pressure of water, let

$$\begin{aligned} t &= \text{thickness of the plate iron in inches;} \\ H &= \text{height of stand-pipe in feet;} \\ D &= \text{diameter of stand-pipe in feet.} \end{aligned}$$

Then, assuming a tensile strength of 48,000 lbs. per square inch, a factor of safety of 4, and efficiency of double-riveted lap-joint equalling 0.6 of the strength of the solid plate,

$$t = .00036H \times D; \quad H = \frac{10,000t}{3.6D};$$

which will give safe heights for thicknesses up to  $\frac{5}{8}$  to  $\frac{3}{4}$  of an inch. The same formula may also apply for greater heights and thicknesses within practical limits, if the joint efficiency be increased by triple riveting.

The conditions for the severest overturning wind strains exist when the stand-pipe is empty.

Formula for wind-pressure of 50 pounds per square foot, when

$$\begin{aligned} d &= \text{diameter of stand-pipe in inches;} \\ x &= \text{any unknown height of stand-pipe;} \\ x &= \sqrt{80\pi dt} = 15.85 \sqrt{dt}. \end{aligned}$$

The following table is calculated by these formulæ. The stand-pipe is intended to be self-sustaining; that is, without guys or stiffeners.

### Heights of Stand-pipes for Various Diameters and Thicknesses of Plates.

Heights to nearest 5 feet. Rings are to build 5 feet vertically.

**Failures of Stand-pipes** have been numerous in recent years. A list showing 23 important failures inside of nine years is given in a paper by Prof. W. D. Pence, *Eng'g. News*, April 5, 12, 19 and 26, May 3, 10 and 24, and June 7, 1894. His discussion of the probable causes of the failures is most valuable.

Kenneth Allen, Engineers Club of Philadelphia, 1886, gives the following rules for thickness of plates for stand pipes.

Assume: Wrought iron plate T. S. 48,000 pounds in direction of fibre, and T. S. 45,000 pounds across the fibre. Strength of single riveted joint .4 that of the plate, and of double riveted joint, .7 that of the plate; wind pressure = 50 pounds per square foot; safety factor = 3.

Let  $h$  = total height in feet;  $r$  = outer radius in feet;  $r'$  = inner radius in feet;  $p$  = pressure per square inch;  $t$  = thickness in inches;  $d$  = outer diameter in feet.

Then for pipe filled and longitudinal seams double riveted

$$t = \frac{pr \times 12}{48,000 \times .7 \times \frac{1}{3}} = \frac{hd}{4301};$$

and for pipe empty and lateral seams, single riveted, we have by equating moments :

$$50 \times 2r \left(\frac{h}{2}\right)^2 = 144 \times 6000 (r^4 - r'^4) \frac{.7854}{r}, \text{ whence } r^4 - r'^4 = \frac{h^2 r^2}{27144}.$$

**Table showing required Thickness of Bottom Plate.**

Height in Feet.	Diameter.

\* The minimum thickness should = 3-16".

N.B.—Dimensions marked † determined by wind-pressure.

**Water Tower at Yonkers, N. Y.**—This tower, with a pipe 122 feet high and 20 feet diameter, is described in *Engineering News*, May 18, 1892.

The thickness of the lower rings is 11-16 of an inch, based on a tensile strength of 60,000 lbs. per square inch of metal, allowing 65% for the strength of riveted joints, using a factor of safety of 3 1/2 and adding a constant of 1/8 inch. The plates diminish in thickness by 1-16 inch to the last four plates at the top, which are 1/4 inch thick.

The contract for steel requires an elastic limit of at least 33,000 lbs. per square inch; an ultimate tensile strength of from 56,000 to 66,000 lbs. per square inch; an elongation in 8 inches of at least 20%, and a reduction of area of at least 45%. The inspection of the work was made by the Pittsburgh Testing Laboratory. According to their report the actual conditions developed were as follows: Elastic limit from 34,020 to 39,420; the tensile strength from 58,330 to 65,390; the elongation in 8 inches from 22 1/2 to 32%; reduction in area from 52.72 to 71.32%; 17 plates out of 141 were rejected in the inspection.

**WROUGHT-IRON AND STEEL WATER-PIPES.**

**Riveted Steel Water-pipes** (*Engineering News*, Oct. 11, 1890, and Aug. 1, 1891.)—The use of riveted wrought-iron pipe has been common in the Pacific States for many years, the largest being a 44-inch conduit in connection with the works of the Spring Valley Water Co., which supplies San Francisco. The use of wrought iron and steel pipe has been necessary in the West, owing to the extremely high pressures to be withstood and the difficulties of transportation. As an example: In connection with

the water supply of Virginia City and Gold Hill, Nev., there was laid in 1872 an 11½-inch riveted wrought-iron pipe, a part of which is under a head of 720 feet.

In the East, the most important example of the use of riveted steel water pipe is that of the East Jersey Water Co., which supplies the city of Newark. The contract provided for a maximum high service supply of 25,000,000 gallons daily. In this case 21 miles of 48-inch pipe was laid, some of it under 340 feet head. The plates from which the pipe is made are about 13 feet long by 7 feet wide, open-hearth steel. Four plates are used to make one section of pipe about 27 feet long. The pipe is riveted longitudinally with a double row, and at the end joints with a single row of rivets of varying diameter, corresponding to the thickness of the steel plates. Before being rolled into the trench, two of the 27-foot lengths are riveted together, thus diminishing still further the number of joints to be made in the trench and the extra excavation to give room for jointing. All changes in the grade of the pipeline are made by 10° curves and all changes in line by 2½, 5, 7½ and 10° curves. To lay on curved lines a standard bevel was used, and the different curves are secured by varying the number of beveled joints used on a certain length of pipe.

The thickness of the plates varies with the pressure, but only three thicknesses are used, ¼, 5-16, and ¾ inches, the pipe made of these thicknesses having a weight of 160, 185, and 225 lbs. per foot, respectively. At the works all the pipe was tested to pressure 1½ times that to which it is to be subjected when in place.

**Mannesmann Tubes for High Pressures.**—At the Mannesmann Works at Komotau, Hungary, more than 600 tons or 25 miles of 3-inch and 4-inch tubes averaging ¼ inch in thickness have been successfully tested to a pressure of 2000 lbs. per square inch. These tubes were intended for a high-pressure water-main in a Chilian nitrate district.

This great tensile strength is probably due to the fact that, in addition to being much more worked than most metal, the fibres of the metal run spirally, as has been proved by microscopic examination. While cast-iron tubes will hardly stand more than 200 lbs. per square inch, and welded tubes are not safe above 1000 lbs. per square inch, the Mannesmann tube easily withstands 2000 lbs. per square inch. The length up to which they can be readily made is shown by the fact that a coil of 3-inch tube 70 feet long was made recently.

For description of the process of making Mannesmann tubes see Trans. A. I. M. E., vol. xix., 384.

### STRENGTH OF VARIOUS MATERIALS. EXTRACTS FROM KIRKALDY'S TESTS.

The recent publication, in a book by W. G. Kirkaldy, of the results of many thousand tests made during a quarter of a century by his father, David Kirkaldy, has made an important contribution to our knowledge concerning the range of variation in strength of numerous materials. A condensed abstract of these results was published in *the American Machinist*, May 11 and 18, 1893, from which the following still further condensed extracts are taken:

The figures for tensile and compressive strength, or, as Kirkaldy calls them, pulling and thrusting stress, are given in pounds per square inch of original section, and for bending strength in pounds of actual stress or pounds per  $BD^2$  (breadth  $\times$  square of depth) for length of 36 inches between supports. The contraction of area is given as a percentage of the original area, and the extension as a percentage in a length of 10 inches, except when otherwise stated. The abbreviations T. S., E. L., Contr., and Ext. are used for the sake of brevity, to represent tensile strength, elastic limit, and percentages of contraction of area, and elongation, respectively.

**Cast Iron.**—44 tests: T. S. 15,468 to 28,740 pounds; 17 of these were unsound, the strength ranging from 15,468 to 24,357 pounds. Average of all, 23,805 pounds.

Thrusting stress, specimens 2 inches long, 1.34 to 1.5 in. diameter; 43 tests, all sound, 94,352 to 131,912; one, unsound, 93,759; average of all, 113,825.

Bending stress, bars about 1 in. wide by 2 in. deep, cast on edge. Ultimate stress 2876 to 3854; stress per  $BD^2 = 725$  to 892; average, 820. Average modulus of rupture,  $R = 3/2$  stress per  $BD^2 \times$  length, = 44,280. Ultimate deflection, .29 to .40 in.; average, .34 inch.

Other tests of cast iron, 460 tests, 16 lots from various sources, gave re-

sults with total range as follows: Pulling stress, 12,688 to 33,616 pounds; thrusting stress, 66,363 to 175,950 pounds; bending stress, per  $BD^2$ , 505 to 1128 pounds; modulus of rupture,  $R$ , 27,270 to 61,912. Ultimate deflection, .21 to .45 inch.

The specimen which was the highest in thrusting stress was also the highest in bending, and showed the greatest deflection, but its tensile strength was only 26,502.

The specimen with the highest tensile strength had a thrusting stress of 143,939, and a bending strength, per  $BD^2$ , of 979 pounds with 0.41 deflection. The specimen lowest in T. S. was also lowest in thrusting and bending, but gave .38 deflection. The specimen which gave .21 deflection had T. S., 19,188; thrusting, 104,281; and bending, 561.

**Iron Castings.**—69 tests; tensile strength, 10,416 to 31,652; thrusting stress, ultimate per square inch, 53,502 to 132,031.

**Channel Irons.**—Tests of 18 pieces cut from channel irons. T. S. 40,693 to 53,141 pounds per square inch; contr. of area from 3.9 to 32.5 %. Ext. in 10 in. from 2.1 to 22.5 %. The fractures ranged all the way from 100 % fibrous to 100 % crystalline. The highest T. S., 53,141, with 8.1 % contr. and 5.3 % ext., was 100 % crystalline; the lowest T. S., 40,693, with 3.9 contr. and 2.1 % ext., was 75 % crystalline. All the fibrous irons showed from 12.2 to 22.5 % ext., 17.3 to 32.5 contr., and T. S. from 43,426 to 49,615. The fibrous irons are therefore of medium tensile strength and high ductility. The crystalline irons are of variable T. S., highest to lowest, and low ductility.

**Lowmoor Iron Bars.**—Three rolled bars  $2\frac{1}{2}$  inches diameter; tensile tests: elastic, 23,200 to 24,200; ultimate, 50,875 to 51,905; contraction, 44.4 to 42.5; extension, 29.2 to 24.3. Three hammered bars,  $4\frac{1}{2}$  inches diameter, elastic 25,100 to 24,200; ultimate, 46,810 to 49,223; contraction, 20.7 to 46.5; extension, 10.8 to 31.6. Fractures of all, 100 per cent fibrous. In the hammered bars the lowest T. S. was accompanied by lowest ductility.

**Iron Bars, Various.**—Of a lot of 80 bars of various sizes, some rolled and some hammered (the above Lowmoor bars included) the lowest T. S. (except one) 40,808 pounds per square inch, was shown by the Swedish "hoop L" bar  $3\frac{1}{4}$  inches diameter, rolled. Its elastic limit was 19,150 pounds; contraction 68.7 % and extension 37.7 % in 10 inches. It was also the most ductile of all the bars tested, and was 100 % fibrous. The highest T. S., 60,780 pounds, with elastic limit, 29,400; contr., 36.6; and ext., 24.3 %, was shown by a "Farnley" 2-inch bar, rolled. It was also 100 % fibrous. The lowest ductility 2.6 % contr., and 4.1 % ext., was shown by a  $3\frac{3}{4}$ -inch hammered bar, without brand. It also had the lowest T. S., 40,278 pounds, but rather high elastic limit, 25,700 pounds. Its fracture was 95 % crystalline. Thus of the two bars showing the lowest T. S., one was the most ductile and the other the least ductile in the whole series of 80 bars.

Generally, high ductility is accompanied by low tensile strength, as in the Swedish bars, but the Farnley bars showed a combination of high ductility and high tensile strength.

**Locomotive Forgings, Iron.**—17 tests: average, E. L., 30,420; T. S., 50,521; contr., 36.5; ext. in 10 inches, 23.8.

**Broken Anchor Forgings, Iron.**—4 tests: average, E. L., 23,825; T. S., 40,083; contr., 3.0; ext. in 10 inches, 3.8.

Kirkaldy places these two irons in contrast to show the difference between good and bad work. The broken anchor material, he says, is of a most treacherous character, and a disgrace to any manufacturer.

**Iron Plate Girder.**—Tensile tests of pieces cut from a riveted iron girder after twenty years' service in a railway bridge. Top plate, average of 3 tests, E. L., 26,600; T. S., 40,806; contr. 16.1; ext. in 10 inches, 7.8. Bottom plate, average of 3 tests, E. L., 31,200; T. S., 44,288; contr., 13.3; ext. in 10 inches, 6.3. Web-plate, average of 3 tests, E. L., 28,000; T. S., 45,902; contr., 15.9; ext. in 10 inches, 8.9. Fractures all fibrous. The results of 30 tests from different parts of the girder prove that the iron has undergone no change during twenty years of use.

**Steel Plates.**—Six plates 100 inches long, 2 inches wide, thickness various, .36 to .97 inch. T. S., 55,485 to 60,805; E. L., 29,600 to 33,200; contr., 52.9 to 59.5; ext., 17.05 to 18.57.

**Steel Bridge Links.**—40 links from Hammersmith Bridge, 1886.

	T. S.	E. L.	Contr.	Ext. in 100 in.	Fracture.	
					Silky.	Granular.
Average of all.....	67,294	38,294	34.5%	14.11%		
Lowest T. S.....	60,753	36,030	30.1	15.51	30%	70%
Highest T. S. and E. L.....	75,936	44,166	31.2	12.42	15	85
Lowest E. L.....	64,044	32,441	34.7	13.43	30	70
Greatest Contraction.....	63,745	38,118	52.8	15.46	100	0
Greatest Extension.....	65,980	36,792	40.8	17.78	35	65
Least Contr. and Ext.....	63,980	39,017	6.0	6.62	0	100

The ratio of elastic to ultimate strength ranged from 50.6 to 65.2 per cent; average, 56.9 per cent.

Extension in lengths of 100 inches. At 10,000 lbs. per sq. in., .018 to .024; mean, .020 inch; at 20,000 lbs. per sq. in. .049 to .063; mean, .055 inch; at 30,000 lbs. per sq. in., .083 to .100; mean, .090; set at 30,000 pounds per sq. in., 0 to .002; mean, 0.

The mean extension between 10,000 to 30,000 lbs. per sq. in. increased regularly at the rate of .007 inch for each 2000 lbs. per sq. in. increment of strain. This corresponds to a modulus of elasticity of 28,571,429. The least increase of extension for an increase of load of 20,000 lbs. per sq. in., .065 inch, corresponds to a modulus of elasticity of 30,769,231, and the greatest, .076 inch, to a modulus of 26,315,789.

**Steel Rails.**—Bending tests, 5 feet between supports, 11 tests of flange rails 72 pounds per yard, 4.63 inches high.

	Elastic stress. Pounds.	Ultimate stress. Pounds.	Deflection at 50,000 Pounds.	Ultimate Deflection.
Hardest....	34,200	60,960	3.24 ins.	8 ins.
Softest ....	32,000	56,740	3.76 "	8 "
Mean .....	32,763	59,209	3.53 "	8 "

All uncracked at 8 inches deflection.

Pulling tests of pieces cut from same rails. Mean results.

	Elastic Stress. per sq. in.	Ultimate Pounds. per sq. in.	Contraction of area of frac- ture.	Extension in 10 ins.
Top of rails.....	44,200	83,110	19.9%	13.5%
Bottom of rails. ....	40,900	77,820	30.9%	22.8%

**Steel Tires.**—Tensile tests of specimens cut from steel tires.

KRUPP STEEL.—262 Tests.

	E. L.	T. S.	Contr.	Ext. in 5 inches.
Highest.....	69,250	119,079	31.9	18.1
Mean .....	52,869	104,112	29.5	19.7
Lowest.....	41,700	90,523	45.5	23.7

VICKERS, SONS & Co.—70 Tests.

	E. L.	T. S.	Contr.	Ext. in 5 inches.
Highest.....	58,600	120,789	11.8	8.4
Mean.....	51,066	101,264	17.6	12.4
Lowest.....	43,700	87,697	24.7	16.0

Note the correspondence between Krupp's and Vickers' steels as to tensile strength and elastic limit, and their great difference in contraction and elongation. The fractures of the Krupp steel averaged 22 per cent silky, 78 per cent granular; of the Vicker steel, 7 per cent silky, 93 per cent granular.

**Steel Axles.**—Tensile tests of specimens cut from steel axles.

PATENT SHAFT AND AXLE TREE Co.—157 Tests.

	E. L.	T. S.	Contr.	Ext. in 5 inches.
Highest.....	49,800	99,009	21.1	16.0
Mean.....	36,267	72,099	33.0	23.6
Lowest. ....	31,800	61,382	34.8	25.3

VICKERS, SONS &amp; Co.—125 Tests.

	E. L.	T. S.	Contr.	Ext. in 5 inches.
Highest.....	42,600	83,701	18.9	13.2
Mean. ....	37,618	70,572	41.6	27.5
Lowest....	30,250	56,388	49.0	37.2

The average fracture of Patent Shaft and Axle Tree Co. steel was 33 per cent silky, 67 per cent granular.

The average fracture of Vickers' steel was 88 per cent silky, 12 per cent granular.

Tensile tests of specimens cut from locomotive crank axles.

VICKERS'.—82 Tests, 1879.

	E. L.	T. S.	Contr.	Ext. in 5 inches.
Highest.....	26,700	68,057	28.3	18.4
Mean .....	24,146	57,922	32.9	24.0
Lowest .....	21,700	50,195	52.7	36.2

VICKERS'.—78 Tests, 1884.

	E. L.	T. S.	Contr.	Ext. in 5 inches.
Highest.....	27,600	64,873	27.0	20.8
Mean .....	23,573	56,207	32.7	25.9
Lowest....	17,600	47,695	35.0	27.2

FRIED. KRUPP.—43 Tests, 1889.

	E. L.	T. S.	Contr.	Ext. in 5 inches.
Highest.....	31,650	66,868	48.6	35.6
Mean .....	29,491	61,774	47.7	32.3
Lowest .....	21,950	55,172	55.3	35.6

**Steel Propeller Shafts.**—Tensile tests of pieces cut from two shafts, mean of four tests each. Hollow shaft, Whitworth, T. S., 61,290; E. L., 30,575; contr., 52.8; ext. in 10 inches, 28.6. Solid Shaft, Vickers', T. S., 46,870; E. L. 20,425; contr., 44.4; ext. in 10 inches, 30.7.

Thrusting tests, Whitworth, ultimate, 56,201; elastic, 29,300; set at 30,000 lbs., 0.18 per cent; set at 40,000 lbs., 2.04 per cent; set at 50,000 lbs., 3.82 per cent.

Thrusting tests, Vickers', ultimate, 44,602; elastic, 22,250; set at 30,000 lbs., 2.29 per cent; set at 40,000 lbs., 4.69 per cent.

Shearing strength of the Whitworth shaft, mean of four tests, was 40,654 lbs. per square inch, or 66.3 per cent of the pulling stress. Specific gravity of the Whitworth steel, 7.867; of the Vickers', 7.856.

**Spring Steel.**—Untempered, 6 tests, average, E. L., 67,916; T. S., 115,668; contr., 37.8; ext. in 10 inches, 16.6. Spring steel untempered, 15 tests, average, E. L., 38,785; T. S., 69,496; contr., 19.1; ext. in 10 inches, 29.8. These two lots were shipped for the same purpose, viz., railway carriage leaf springs.

**Steel Castings.**—44 tests, E. L., 31,816 to 35,567; T. S., 54,928 to 63,840; contr., 1.67 to 15.8; ext., 1.45 to 15.1. Note the great variation in ductility. The steel of the highest strength was also the most ductile.

**Riveted Joints, Pulling Tests of Riveted Steel Plates,  
Triple Riveted Lap Joints, Machine Riveted,  
Holes Drilled.**

Plates, width and thickness, inches :	13.50 × .25	13.00 × .51	11.75 × .78	12.25 × 1.01	14.00 × .77
Plates, gross sectional area square inches :	3.375	6.63	9.165	12.372	10.780
Stress, total, pounds :	199,320	332,640	423,180	528,000	455,210

**Wire.**—Tensile Strength.

German silver, 5 lots.....	81,735 to 92,224
Bronze, 1 lot.....	78,049
Brass, as drawn, 4 lots.....	81,114 to 98,578
Copper, as drawn, 3 lots.....	37,607 to 46,494
Copper annealed, 3 lots.....	34,936 to 45,210
Copper (another lot), 4 lots.....	35,052 to 62,190
Copper (extension 36.4 to 0.6%).	
Iron, 8 lots.....	59,246 to 97,908
Iron (extension 15.1 to 0.7%).	
Steel, 8 lots.....	103,272 to 318,823

The Steel of 318,823 T. S. was .047 inch diam., and had an extension of only 0.3 per cent; that of 103,272 T. S. was .107 inch diam. and had an extension of 2.2 per cent. One lot of .044 inch diam. had 267,114 T. S., and 5.2 per cent extension.

**Wire Ropes.**

## Selected Tests Showing Range of Variation.

Description.	Circumference, inches.	Weight per Fathom.	Strands.		Diameter of Wires, inches.	Hemp Core.	Ultimate Strength, lbs.
			No. of Strands.	No. of Wires.

Galvanized.....	1.76	1.85	6	12	.0305	Main	14,634

**Hemp Ropes, Untarred.**—15 tests of ropes from 1.53 to 6.90 inches circumference, weighing 0.42 to 7.77 pounds per fathom, showed an ultimate strength of from 1670 to 33,808 pounds, the strength per fathom weight varying from 2872 to 5534 pounds.

**Hemp Ropes, Tarred.**—15 tests of ropes from 1.44 to 7.12 inches circumference, weighing from 0.38 to 10.39 pounds per fathom, showed an ultimate strength of from 1046 to 31,549 pounds, the strength per fathom weight varying from 1767 to 5149 pounds.

**Cotton Ropes.**—5 ropes, 2.48 to 6.51 inches circumference, 1.08 to 8.17 pounds per fathom. Strength 3089 to 23,258 pounds, or 2474 to 3346 pounds per fathom weight.

**Manila Ropes.**—35 tests: 1.19 to 8.90 inches circumference, 0.20 to 11.40 pounds per fathom. Strength 1230 to 65,550 pounds, or 3003 to 7394 pounds per fathom weight.

**Belting.**

No. of lots.		Tensile strength per square inch.
11	Leather, single, ordinary tanned .....	3248 to 4824
4	Leather, single, Helvetia .....	5631 to 5944
7	Leather, double, ordinary tanned.....	2160 to 3572
8	Leather, double Helvetia.....	4078 to 5412
6	Cotton, solid woven.....	5648 to 8869
14	Cotton, folded, stitched .....	4570 to 7750
1	Flax, solid, woven .....	9946
1	Flax, folded, stitched.....	6389
6	Hair, solid, woven.....	3852 to 5159
2	Rubber, solid, woven.....	4271 to 4343

**Canvas.**—35 lots: Strength, lengthwise, 113 to 408 pounds per inch; crossways, 191 to 468 pounds per inch.

The grades are numbered 1 to 6, but the weights are not given. The strengths vary considerably, even in the same number.

**Marbles.**—Crushing strength of various marbles. 38 tests, 8 kinds. Specimens were 6-inch cubes, or columns 4 to 6 inches diameter, and 6 and 12 inches high. Range 7542 to 13,720 pounds per square inch.

**Granite.**—Crushing strength, 17 tests; square columns 4 × 4 and 6 × 4, 4 to 24 inches high, 3 kinds. Crushing strength ranges 10,026 to 13,271 pounds per square inch. (Very uniform.)

**Stones.**—(Probably sandstone, local names only given.) 11 kinds, 49 tests, 6 × 6, columns 12, 18 and 24 inches high. Crushing strength ranges from 2105 to 12,122. The strength of the column 24 inches long is generally from 10 to 20 per cent less than that of the 6-inch cube.

**Stones.**—(Probably sandstone) tested for London & Northwestern Railway. 16 lots, 3 to 6 tests in a lot. Mean results of each lot ranged from 3785 to 11,956 pounds. The variation is chiefly due to the stones being from different lots. The different specimens in each lot gave results which generally agreed within 30 per cent.

**Bricks.**—Crushing strength, 8 lots; 6 tests in each lot; mean results ranged from 1835 to 9209 pounds per square inch. The maximum variation in the specimens of one lot was over 100 per cent of the lowest. In the most uniform lot the variation was less than 20 per cent.

**Wood.**—Transverse and Thrusting Tests.

	Tests.	Sizes abt. in square.	Span, inches.	Ultimate Stress.	$S = \frac{LW}{4BD^2}$ .	Thrusting Stress per sq. in.
Pitch pine.....	10	11½ to 12½	144	45,856 to 80,520 37,948	1096 to 1403 657	3586 to 5438 2478
Dantzic fir.....	12	12 to 13	144	to 54,152 32,856	to 790 1505	to 3423 2473
English oak.....	3	4½ × 12	120	to 39,084 23,624	to 1779 1190	to 4437 2656
American white oak .....	5	4½ × 12	120	to 26,952	to 1372	to 3890

Demerara greenheart, 9 tests (thrusting).....	8169 to 10,785
Oregon pine, 2 tests.....	5888 and 7284
Honduras mahogany, 1 test.....	6769
Tobasco mahogany, 1 test.....	5978
Norway spruce, 2 tests ..	5259 and 5494
American yellow pine, 2 tests.....	3875 and 3993
English ash, 1 test.....	3025

**Portland Cement.**—(Austrian.) Cross-sections of specimens 2 × 2½ inches for pulling tests only; cubes, 3 × 3 inches for thrusting tests; weight,

98.8 pounds per imperial bushel; residue, 0.7 per cent with sieve 2500 meshes per square inch; 38.8 per cent by volume of water required for mixing; time of setting, 7 days; 10 tests to each lot. The mean results in lbs. per sq. in. were as follows:

Age.	Cement alone, Pulling.	Cement alone, Thrusting.	1 Cement, 2 Sand, Thrusting.	1 Cement, 3 Sand, Thrusting.	1 Cement, 4 Sand, Thrusting.
10 days	376	2910	893	407	228
20 days	420	3342	1023	494	275
30 days	451	3724	1172	594	338

**Portland Cement.**—Various samples pulling tests, 2 × 2½ inches cross-section, all aged 10 days, 180 tests; ranges 87 to 643 pounds per square inch.

**TENSILE STRENGTH OF WIRE.**

(From J. Bucknall Smith's Treatise on Wire.)

	Tons per sq. in. sectional area.	Pounds per sq. in. sectional area.
Black or annealed iron wire.....	25	56,000
Bright hard drawn.....	35	78,400
Bessemer, steel wire.....	40	89,600
Mild Siemens-Martin steel wire.....	60	134,000
High carbon ditto (or "improved") ...	80	179,200
Crucible cast-steel "improved" wire... ..	100	224,000
"Improved" cast-steel "plough".....	120	268,800

### TENSILE TEST OF SIX STEEL EYE-BARS.

COMPARED WITH SMALL TEST INGOTS.

The steel was made by the Cambria Iron Company, and the eye-bar heads made by Keystone Bridge Company by upsetting and hammering. All the bars were made from one ingot. Two test pieces, ¾-inch round, rolled from a test-ingot, gave elastic limit 48,040 and 42,210 pounds; tensile strength, 73,150 and 69,470 pounds, and elongation in 8 inches, 22.4 and 25.6 per cent, respectively. The ingot from which the eye-bars were made was 14 inches square, rolled to billet, 7 × 6 inches. The eye-bars were rolled to 6½ × 1 inch. Chemical tests gave carbon .27 to .30; manganese, .64 to .73; phosphorus, .074 to .098.

Gauged Length, inches.	Elastic limit, lbs. per sq. in.	Tensile strength per sq. in., lbs.	Elongation per cent, in Gauged Length.
160	37,480	67,800	15.8
160	36,650	64,000	6.96
160	.....	71,560	8.6
200	37,600	68,720	12.3
200	35,810	65,850	12.0
200	33,230	64,410	16.4
200	37,640	68,290	13.9

The average tensile strength of the ¾-inch test pieces was 71,310 lbs., that of the eye-bars 67,230 lbs., a decrease of 5.7%. The average elastic limit of the test pieces was 45,150 lbs., that of the eye-bars 36,402 lbs., a decrease of 19.4%. The elastic limit of the test pieces was 63.3% of the ultimate strength, that of the eye-bars 54.2% of the ultimate strength.

EFFECT OF COLD-DRAWING ON STEEL

Three pieces cut from the same bar of hot-rolled steel:

1. Original bar, 2.03 in. diam., gauged length 30 in., tensile strength 55,400 lbs. per square in.; elongation 23.9%.
2. Diameter reduced in compression dies (one pass) .094 in.; T. S. 70,420; el. 2.7% in 20 in.
3. " " " " " " " " " " .222 in.; T. S. 81,890; el. 0.075% in 20 in.

Compression test of cold-drawn bar (same as No. 3), length 4 in., diam. 1.808 in.; Compressive strength per sq. in., 75,000 lbs.; amount of compression .057 in.; set .04 in. Diameter increased by compression to 1.821 in. in the middle; to 1.813 in. at the ends.

**Tests of Cold-rolled and Cold-drawn Steel**, made by the Cambria Iron Co. in 1897, gave the following results (averages of 12 tests of each):

Before cold-rolling, E. L.	35,390	T. S.	59,980	El. in 8 in.	28.3%	Red.	58.5%
After " " " "	72,530	"	79,830	" "	9.6 "	"	34.9 "
After cold-drawing, " "	76,350	"	83,860	" "	8.9 "	"	34.2 "

The original bars were 2 in. and 7/8 in. diameter. The test pieces cut from the bars were 3/4 in. diam., 18 in. long. The reduction in diameter from the hot-rolled to the cold-rolled or cold-drawn bar was 1/16 in. in each case.

## TESTS OF AMERICAN WOODS. (See also page 309.)

In all cases a large number of tests were made of each wood. Minimum and maximum results only are given. All of the test specimens had a sectional area of  $1.575 \times 1.575$  inches. The transverse test specimens were 39.37 inches between supports, and the compressive test specimens were 12.60 inches long. Modulus of rupture calculated from formula  $R = \frac{3}{2} \frac{Pl}{bd^2}$ ;  $P$  = load in pounds at the middle,  $l$  = length in inches,  $b$  = breadth,  $d$  = depth:

Name of Wood.	Transverse Tests. Modulus of Rupture.		Compression Parallel to Grain, pounds per square inch.

## SHEARING STRENGTH OF IRON AND STEEL.

H. V. Loss in *American Engineer and Railroad Journal*, March and April, 1893, describes an extensive series of experiments on the shearing of iron and steel bars in shearing machines. Some of his results are:

Depth of penetration at point of maximum resistance for soft steel bars is independent of the width, but varies with the thickness. If  $d$  = depth of penetration and  $t$  = thickness,  $d = .3t$  for a flat knife,  $d = .25 t$  for a 4° bevel knife, and  $d = .16 \sqrt[3]{t^3}$  for an 8° bevel knife. The ultimate pressure per inch of width in flat steel bars is approximately 50,000 lbs.  $\times t$ . The energy consumed in foot pounds per inch width of steel bars is, approximately: 1" thick, 1300 ft.-lbs.; 1½", 2500; 1¾", 3700; 1⅞", 4500; the energy increasing at a slower rate than the square of the thickness. Iron angles require more energy than steel angles of the same size; steel breaks while iron has to be cut off. For hot-rolled steel the resistance per square inch for rectangular sections varies from 4400 lbs. to 20,500 lbs., depending partly upon its hardness and partly upon the size of its cross-area, which latter element indirectly but greatly indicates the temperature, as the smaller dimensions require a considerably longer time to reduce them down to size, which time again means loss of heat.

It is not probable that the resistance in practice can be brought very much below the lowest figures here given—viz., 4400 lbs. per square inch—as a decrease of 1000 lbs. will henceforth mean a considerable increase in cross-section and temperature.

**HOLDING-POWER OF BOILER-TUBES EXPANDED INTO TUBE-SHEETS.**

Experiments by Chief Engineer W. H. Shock, U. S. N., on brass tubes, 2¼ inches diameter, expanded into plates ¾-inch thick, gave results ranging from 5850 to 46,000 lbs. Out of 48 tests 5 gave figures under 10,000 lbs., 12 between 10,000 and 20,000 lbs., 18 between 20,000 and 30,000 lbs., 10 between 30,000 and 40,000 lbs., and 3 over 40,000 lbs.

Experiments by Yarrow & Co., on steel tubes, 2 to 2¼ inches diameter, gave results similarly varying, ranging from 7900 to 41,715 lbs., the majority ranging from 20,000 to 30,000 lbs. In 15 experiments on 4 and 5 inch tubes the strain ranged from 20,720 to 68,040 lbs. Beading the tube does not necessarily give increased resistance, as some of the lower figures were obtained with beaded tubes. (See paper on Rules Governing the Construction of Steam Boilers, Trans. Engineering Congress, Section G, Chicago, 1893.)

**Wrought-iron Chain Cables.**—The strength of a chain link is less than twice that of a straight bar of a sectional area equal to that of one side of the link. A weld exists at one end and a bend at the other, each requiring at least one heat, which produces a decrease in the strength. The report of the committee of the U. S. Testing Board, on tests of wrought-iron and chain cables contains the following conclusions. That beyond doubt, when made of American bar iron, with cast-iron studs, the studded link is inferior in strength to the unstudded one.

“That when proper care is exercised in the selection of material, a variation of 5 to 17 per cent of the strongest may be expected in the resistance of cables. Without this care, the variation may rise to 25 per cent.

“That with proper material and construction the ultimate resistance of the chain may be expected to vary from 155 to 170 per cent of that of the bar used in making the links, and show an average of about 163 per cent.

“That the proof test of a chain cable should be about 50 per cent of the ultimate resistance of the weakest link.”

The decrease of the resistance of the studded below the unstudded cable is probably due to the fact that in the former the sides of the link do not remain parallel to each other up to failure, as they do in the latter. The result is an increase of stress in the studded link over the unstudded in the proportion of unity, to the secant of half the inclination of the sides of the former to each other.

From a great number of tests of bars and unfinished cables, the committee considered that the average ultimate resistance, and proof tests of chain cables made of the bars, whose diameters are given, should be such as are shown in the accompanying table.

ULTIMATE RESISTANCE AND PROOF TESTS OF CHAIN CABLES.

Diam. of Bar.	Average resist. = 163% of Bar.	Proof Test.	Diam. of Bar.	Average resist. = 163% of Bar.	Proof Test.

### STRENGTH OF GLASS.

(Fairbairn's "Useful Information for Engineers," Second Series.)

	Best Flint Glass.	Common Green Glass.	Extra White Crown Glass.
Mean specific gravity	3.078	2.528	2.450
Mean tensile strength, lbs. per sq. in., bars..	2,413	2,896	2,546
do. thin plates.	4,200	4,800	6,000
Mean crush'g strength, lbs. p. sq. in., cyl'drs.	27,582	39,876	31,003
do. cubes.	13,130	20,206	21,867

The bars in tensile tests were about  $\frac{1}{2}$  inch diameter. The crushing tests were made on cylinders about  $\frac{3}{4}$  inch diameter and from 1 to 2 inches high, and on cubes approximately 1 inch on a side. The mean transverse strength of glass, as calculated by Fairbairn from a mean tensile strength of 2560 lbs. and a mean compressive strength of 30,150 lbs. per sq. in., is, for a bar supported at the ends and loaded in the middle,

$$w = 3140 \frac{bd^2}{l},$$

In which  $w$  = breaking weight in lbs.,  $b$  = breadth,  $d$  = depth, and  $l$  = length, in inches. Actual tests will probably show wide variations in both directions from the mean calculated strength.

**STRENGTH OF COPPER AT HIGH TEMPERATURES.**

The British Admiralty conducted some experiments at Portsmouth Dockyard in 1877, on the effect of increase of temperature on the tensile strength of copper and various bronzes. The copper experimented upon was in rods .72-in. diameter.

The following table shows some of the results:

Temperature Fahr.	Tensile Strength in lbs. per sq. in.	Temperature Fahr.	Tensile Strength in lbs. per sq. in.
Atmospheric.	23,115	300°	21,607
100°	23,366	400°	21,105
200°	22,110	500°	19,597

Up to a temperature of 400° F. the loss of strength was only about 10 per cent, and at 500° F. the loss was 16 per cent. The temperature of steam at 200 lbs. pressure is 382° F., so that according to these experiments the loss of strength at this point would not be a serious matter. Above a temperature of 500° the strength is seriously affected.

**STRENGTH OF TIMBER.**

**Strength of Long-leaf Pine** (Yellow Pine, *Pinus Palustris*) from Alabama (Bulletin No. 8, Forestry Div., Dept. of Agriculture, 1893. Tests by Prof. J. B. Johnson.)

The following is a condensed table of the range of results of mechanical tests of over 2000 specimens, from 26 trees from four different sites in Alabama; reduced to 15 per cent moisture:

	Butt Logs.	Middle Logs.	Top Logs.	Av'g of all Butt Logs.
Specific gravity .....	0.449 to 1.039	0.575 to 0.859	0.484 to 0.907	0.767
Transverse strength, $\frac{3WL}{2bh^2}$	4,762 to 16,200	7,640 to 17,128	4,268 to 15,554	12,614
do do. at elast. limit.	4,930 to 13,110	5,540 to 11,790	2,553 to 11,950	9,460
Mod. of elast., thous. lbs.	1,119 to 3,117	1,136 to 2,982	842 to 2,697	1,926
Relative elast. resilience, inch-pounds per cub. in.	0.23 to 4.69	1.34 to 4.21	2.09 to 4.65	2.98
Crushing endwise, str. per sq. in.-lbs.....	4,781 to 9,850	5,030 to 9,300	4,587 to 9,100	7,452
Crushing across grain, strength per sq. in., lbs.	675 to 2,094	656 to 1,445	584 to 1,766	1,598
Tensile strength per sq. in.	8,600 to 31,890	6,330 to 29,500	4,170 to 23,280	17,359
Shearing strength (with grain), mean per sq. in.	464 to 1,299	539 to 1,230	484 to 1156	866

Some of the deductions from the tests were as follows:

1. With the exception of tensile strength a reduction of moisture is accompanied by an increase in strength, stiffness, and toughness.
2. Variation in strength goes generally hand-in-hand with specific gravity.
3. In the first 20 or 30 feet in height the values remain constant; then occurs a decrease of strength which amounts at 70 feet to 20 to 40 per cent of that of the butt-log.
4. In shearing parallel with the grain and crushing across and parallel with the grain, practically no difference was found.
5. Large beams appear 10 to 20 per cent weaker than small pieces.
6. Compression tests endwise seem to furnish the best average statement of the value of wood, and if one test only can be made, this is the safest, as was also recognized by Bauschinger.
7. Bled timber is in no respect inferior to unbled timber.

The figures for crushing across the grain represent the load required to cause a compression of 15 per cent. The relative elastic resilience, in inch-pounds per cubic inch of the material, is obtained by measuring the area of the plotted-strain diagram of the transverse test from the origin to the point in the curve at which the rate of deflection is 50 per cent greater than the rate in the earlier part of the test where the diagram is a straight line. This point is arbitrarily chosen since there is no definite "elastic limit" in timber as there is in iron. The "strength at the elastic limit" is the strength taken at this same point. Timber is not perfectly elastic for any load if left on any great length of time.

The long-leaf pine is found in all the Southern coast states from North Carolina to Texas. Prof. Johnson says it is probably the strongest timber in large sizes to be had in the United States. In small selected specimens, other species, as oak and hickory, may exceed it in strength and toughness. The other Southern yellow pines, viz., the Cuban, short-leaf and the loblolly pines are inferior to the long-leaf about in the ratios of their specific gravities; the long-leaf being the heaviest of all the pines. It averages (kiln-dried) 48 pounds per cubic foot, the Cuban 47, the short-leaf 40, and the loblolly 34 pounds.

**Strength of Spruce Timber.**—The modulus of rupture of spruce is given as follows by different authors: Hatfield, 9900 lbs. per square inch; Rankine, 11,100; Laslett, 9045; Trautwine, 8100; Rodman, 6168. Trautwine advises for use to deduct one-third in the case of knotty and poor timber.

Prof. Lanza, in 25 tests of large spruce beams, found a modulus of rupture from 2995 to 5666 lbs.; the average being 4613 lbs. These were average beams, ordered from dealers of good repute. Two beams of selected stock, seasoned four years, gave 7562 and 8748 lbs. The modulus of elasticity ranged from 897,000 to 1,588,000, averaging 1,294,000.

Time tests show much smaller values for both modulus of rupture and modulus of elasticity. A beam tested to 5800 lbs. in a screw machine was left over night, and the resistance was found next morning to have dropped to about 3000, and it broke at 3500.

Prof. Lanza remarks that while it was necessary to use larger factors of safety, when the moduli of rupture were determined from tests with smaller pieces, it will be sufficient for most timber constructions, except in factories, to use a factor of four. For breaking strains of beams, he states that it is better engineering to determine as the safe load of a timber beam the load that will not deflect it more than a certain fraction of its span, say about 1/300 to 1/400 of its length.

**Properties of Timber.**

(N. J. Steel & Iron Co.'s Book.)

Description.	Weight per cubic foot, in lbs.	Tensile Strength per sq. inch, in lbs.	Crushing Strength per sq. inch, in lbs.	Relative Strength for Cross Breaking. White Pine = 100.	Shearing Strength with the Grain, lbs. per sq. inch
Ash .....	43 to 55.8	11,000 to 17,297	4,400 to 9,363	130 to 180	458 to 700
Beech.....	43 to 53.4	11,500 to 18,000	5,800 to 9,363	100 to 144	.....
Cedar.....	50 to 56.8	10,200 to 11,400	5,600 to 6,000	55 to 63	.....
Cherry.....	.....	.....	.....	130	.....
Chestnut.....	33	10,500	5,350 to 5,600	96 to 123	.....
Elm.....	34 to 36.7	13,400 to 13,489	6,831 to 10,331	96	.....
Hemlock.....	.....	8,700	5,700	88 to 95	.....
Hickory.....	.....	12,800 to 18,000	8,925	150 to 210	.....
Locust.....	44	20,500 to 24,800	9,113 to 11,700	132 to 227	.....
Maple .. .. .	49	10,500 to 10,584	8,150	122 to 220	367 to 647
Oak, White....	45 to 54.5	10,253 to 19,500	4,684 to 9,509	130 to 177	752 to 966
Oak, Live .....	70	.....	6,850	155 to 189	.....
Pine, White....	30	10,000 to 12,000	5,000 to 6,650	100	225 to 423
Pine, Yellow...	28.8 to 33	12,600 to 19,200	5,400 to 9,500	98 to 170	286 to 415
Spruce.....	.....	10,000 to 19,500	5,050 to 7,850	86 to 110	253 to 374
Walnut, Black.	42	9,286 to 16,000	7,500	.....	.....

The above table should be taken with caution. The range of variation in the species is apt to be much greater than the figures indicate. See Johnson's tests on long-leaf pine, and Lanza's on spruce, above. The weight of yellow pine in the table is much less than that given by Johnson. (W. K.)

**Compressive Strengths of American Woods,** when slowly and carefully seasoned.—Approximate averages, deduced from many experiments made with the U. S. Government testing-machine at Watertown, Mass., by Mr. S. P. Sharpless, for the Census of 1880. Seasoned woods resist crushing much better than green ones; in many cases, twice as well. Different specimens of the same wood vary greatly. The strengths may readily vary as much as one-third part more or less from the average.

### THE STRENGTH OF BRICK, STONE, ETC.

A great advance has recently been made in the manufacture of brick, in the direction of increasing their strength. Chas. P. Chase, in *Engineering News*, says: "Taking the tests as given in standard engineering books eight or ten years ago, we find in Trautwine the strength of brick given as 500 to 4200 lbs. per sq. in. Now, taking recent tests in experiments made at Watertown Arsenal, the strength ran from 5000 to 22,000 lbs per sq. in. In the tests on Illinois paving-brick, by Prof. I. O. Baker, we find an average strength in hard paving brick of over 5000 lbs. per square inch. The average crushing strength of ten varieties of paving-brick much used in the West, I find to be 7150 lbs. to the square inch."

A recent test of brick made by the dry-clay process at Watertown Arsenal, according to *Paving*, showed an average compressive strength of 3972 lbs. per sq. in. In one instance it reached 4973 lbs. per sq. in. A test was made at the same place on a "fancy pressed brick." The first crack developed at a pressure of 305,000 lbs., and the brick crushed at 364,300 lbs., or 11,130 lbs. per sq. in. This indicates almost as great compressive strength as granite paving-blocks, which is from 12,000 to 20,000 lbs. per sq. in.

The following notes on bricks are from Trautwine's *Engineer's Pocket-book*:

**Strength of Brick.**—40 to 300 tons per sq. ft., 622 to 4668 lbs. per sq. in. A soft brick will crush under 450 to 600 lbs. per sq. in., or 30 to 40 tons per square foot, but a first-rate machine-pressed brick will stand 200 to 400 tons per sq. ft. (3112 to 6224 lbs. per sq. in.).

**Weight of Bricks.**—Per cubic foot, best pressed brick, 150 lbs.; good pressed brick, 131 lbs.; common hard brick, 125 lbs.; good common brick, 118 lbs.; soft inferior brick, 100 lbs.

**Absorption of Water.**—A brick will in a few minutes absorb  $\frac{1}{2}$  to  $\frac{3}{4}$  lb. of water, the last being  $\frac{1}{7}$  of the weight of a hand-moulded one, or  $\frac{1}{2}$  of its bulk.

**Tests of Bricks, full size, on flat side.** (Tests made at Watertown Arsenal in 1883.)—The bricks were tested between flat steel buttresses. Compressed surfaces (the largest surface) ground approximately flat. The bricks were all about 2 to 2.1 inches thick, 7.5 to 8.1 inches long, and 3.5 to 3.76 inches wide. Crushing strength per square inch: One lot ranged from 11,056 to 16,734 lbs.; a second, 12,995 to 22,351; a third, 10,390 to 12,709. Other tests gave results from 5960 to 10,250 lbs. per sq. in.

**Crushing Strength of Masonry Materials.** (From Howe's "Retaining-Walls.")

	tons per sq. ft.		tons per sq. ft.
Brick, best pressed ..	40 to 300	Limestones and marbles ..	250 to 1000
Chalk .....	20 to 30	Sandstone .....	150 to 550
Granite .....	300 to 1200	Soapstone .....	400 to 800

**Strength of Granite.**—The crushing strength of granite is commonly rated at 12,000 to 15,000 lbs. per sq. in. when tested in two-inch cubes, and only the hardest and toughest of the commonly used varieties reach a strength above 20,000 lbs. Samples of granite from a quarry on the Con-

necticut River, tested at the Watertown Arsenal, have shown a strength of 35,965 lbs. per sq. in. (*Engineering News*, Jan. 12, 1893).

**Strength of Avondale, Pa., Limestone**—(*Engineering News*, Feb. 9, 1893).—Crushing strength of 2-in. cubes: light stone 12,112, gray stone 18,040, lbs. per sq. in.

Transverse test of lintels, tool-dressed, 42 in. between knife-edge bearings, load with knife-edge brought upon the middle between bearings:

Gray stone, section 6 in. wide × 10 in. high, broke under a load of 20,950 lbs.	
Modulus of rupture.....	2,200 “
Light stone, section 8¼ in. wide × 10 in. high, broke under.....	14,720 “
Modulus of rupture.....	1,170 “
Absorption.—Gray stone.....	.051 of 1%
Light stone.....	.052 of 1%

**Transverse Strength of Flagging.**

(N. J. Steel & Iron Co.'s Book.)

EXPERIMENTS MADE BY R. G. HATFIELD AND OTHERS.

*b* = width of the stone in inches; *d* = its thickness in inches; *l* = distance between bearings in inches.

The *breaking loads* in tons of 2000 lbs., for a weight placed at the *centre* of the space, will be as follows:

	$\frac{bd^2}{l} \times$		$\frac{bd^2}{l} \times$
Bluestone flagging.....	.744	Dorchester freestone.....	.264
Quincy granite.....	.624	Aubigny freestone.....	.216
Little Falls freestone.....	.576	Caen freestone.....	.144
Belleville, N. J., freestone.....	.480	Glass.....	1.000
Granite (another quarry).....	.432	Slate.....	1.2 to 2.7
Connecticut freestone.....	.312		

Thus a block of Quincy granite 80 inches wide and 6 inches thick, resting on beams 36 inches in the clear, would be broken by a load resting midway between the beams =  $\frac{80 \times 36}{36} \times .624 = 49.92$  tons.

**STRENGTH OF LIME AND CEMENT MORTAR.**

(*Engineering*, October 2, 1891.)

Tests made at the University of Illinois on the effects of adding cement to lime mortar. In all the tests a good quality of ordinary fat lime was used, slaked for two days in an earthenware jar, adding two parts by weight of water to one of lime, the loss by evaporation being made up by fresh additions of water. The cements used were a German Portland, Black Diamond (Louisville), and Rosendale. As regards fineness of grinding, 85 per cent of the Portland passed through a No. 100 sieve, as did 72 per cent of the Rosendale. A fairly sharp sand, thoroughly washed and dried, passing through a No. 18 sieve and caught on a No. 30, was used. The mortar in all cases consisted of two volumes of sand to one of lime paste. The following results were obtained on adding various percentages of cement to the mortar:

**Tensile Strength, pounds per square inch.**

Age.....	Days.						
	4	7	14	21	28	50	84
Lime mortar.....	4	8	10	13	18	21	26

**MODULI OF ELASTICITY OF VARIOUS MATERIALS.**

The modulus of elasticity determined from a tensile test of a bar of any material is the quotient obtained by dividing the tensile stress in pounds per square inch at any point of the test by the elongation per inch of length produced by that stress; or if  $P$  = pounds of stress applied,  $K$  = the sectional area,  $l$  = length of the portion of the bar in which the measurement is made, and  $\lambda$  = the elongation in that length, the modulus of elasticity  $E = \frac{P}{K} \div \frac{\lambda}{l} = \frac{Pl}{K\lambda}$ . The modulus is generally measured within the

elastic limit only, in materials that have a well-defined elastic limit, such as iron and steel, and when not otherwise stated the modulus is understood to be the modulus within the elastic limit. Within this limit, for such materials the modulus is practically constant for any given bar, the elongation being directly proportional to the stress. In other materials, such as cast iron, which have no well-defined elastic limit, the elongations from the beginning of a test increase in a greater ratio than the stresses, and the modulus is therefore at its maximum near the beginning of the test, and continually decreases. The moduli of elasticity of various materials have already been given above in treating of these materials, but the following table gives some additional values selected from different sources:

Brass, cast.....	9,170,000		
“ wire.....	14,230,000		
Copper.....	15,000,000	to 18,000,000	
Lead.....	1,000,000

Beech.....	1,300,000		
Birch.....	1,250,000	to 1,500,000	
Fir.....	869,000	to 2,191,000	
Oak.....	974,000	to 2,283,000	
Teak.....	2,414,000		
Walnut.....	306,000		
Pine, long-leaf (butt-logs)...	1,119,000	to 3,117,000	Ave. 1,926,000

The maximum figures given by many writers for iron and steel, viz., 40,000,000 and 42,000,000, are undoubtedly erroneous. The modulus of elasticity of steel (within the elastic limit) is remarkably constant, notwithstanding great variations in chemical analysis, temper, etc. It rarely is found below 29,000,000 or above 31,000,000. It is generally taken at 30,000,000 in engineering calculations. Prof. J. B. Johnson, in his report on Long-leaf Pine, 1893, says: “The modulus of elasticity is the most constant and reliable property of all engineering materials. The wide range of value of the modulus of elasticity of the various metals found in public records must be explained by erroneous methods of testing.”

In a tensile test of cast iron by the author (Van Nostrand's Science Series, No. 41, page 45), in which the ultimate strength was 23,285 lbs. per sq. in., the measurements of elongation were made to .0001 inch, and the modulus of elasticity was found to decrease from the beginning of the test, as follows: At 1000 lbs. per sq. in., 25,000,000; at 2000 lbs., 16,666,000; at 4000 lbs., 15,384,000; at 6000 lbs., 13,636,000; at 8000 lbs., 12,500,000; at 12,000 lbs., 11,250,000; at 15,000 lbs., 10,000,000; at 20,000 lbs., 8,000,000; at 23,000 lbs., 6,140,000.

**FACTORS OF SAFETY.**

A factor of safety is the ratio in which the load that is just sufficient to overcome instantly the strength of a piece of material is greater than the greatest safe ordinary working load. (Rankine.)

Rankine gives the following “examples of the values of those factors which occur in machines”:

	Dead Load.	Live Load, Greatest.	Live Load, Mean.
Iron and steel.....	3	6	from 6 to 40
Timber.....	4 to 5	8 to 10	....
Masonry.....	4	8	....

The great factor of safety, 40, is for shafts in millwork which transmit very variable efforts.

Unwin gives the following "factors of safety which have been adopted in certain cases for different materials." They "include an allowance for ordinary contingencies."

	Dead Load.	Live Load.		
		In Temporary Structures.	In Permanent Structures.	In Structures subj. to Shocks.
Wrought iron and steel.	3	4	4 to 5	10
Cast iron.....	3	4	5	10
Timber.....	....	4	10	....
Brickwork.....	....	....	6	....
Masonry.....	20	....	20 to 30	....

Unwin says that "these numbers fairly represent practice based on experience in many actual cases, but they are not very trustworthy."

Prof. Wood in his "Resistance of Materials" says: "In regard to the margin that should be left for safety, much depends upon the character of the loading. If the load is simply a dead weight, the margin may be comparatively small; but if the structure is to be subjected to percussive forces or shocks, the margin should be comparatively large on account of the indeterminate effect produced by the force. In machines which are subjected to a constant jar while in use, it is very difficult to determine the proper margin which is consistent with economy and safety. Indeed, in such cases, economy as well as safety generally consists in making them *excessively* strong, as a single breakage may cost much more than the extra material necessary to fully insure safety."

For discussion of the resistance of materials to repeated stresses and shocks, see pages 238 to 240.

Instead of using factors of safety it is becoming customary in designing to fix a certain number of pounds per square inch as the maximum stress which will be allowed on a piece. Thus, in designing a boiler, instead of naming a factor of safety of 6 for the plates and 10 for the stay-bolts, the ultimate tensile strength of the steel being from 50,000 to 60,000 lbs. per sq. in., an allowable working stress of 10,000 lbs. per sq. in. on the plates and 6000 lbs. per sq. in. on the stay-bolts may be specified instead. So also in Merriman's formula for columns (see page 260) the dimensions of a column are calculated after assuming a maximum allowable compressive stress per square inch on the concave side of the column.

The factors for masonry under dead load as given by Rankine and by Unwin, viz., 4 and 20, show a remarkable difference, which may possibly be explained as follows: If the actual crushing strength of a pier of masonry is known from direct experiment, then a factor of safety of 4 is sufficient for a pier of the same size and quality under a steady load; but if the crushing strength is merely assumed from figures given by the authorities (such as the crushing strength of pressed brick, quoted above from Howe's Retaining Walls, 40 to 300 tons per square foot, average 170 tons), then a factor of safety of 20 may be none too great. In this case the factor of safety is really a "factor of ignorance."

The selection of the proper factor of safety or the proper maximum unit stress for any given case is a matter to be largely determined by the judgment of the engineer and by experience. No definite rules can be given. The customary or advisable factors in many particular cases will be found where these cases are considered throughout this book. In general the following circumstances are to be taken into account in the selection of a factor:

1. When the ultimate strength of the material is known within narrow limits, as in the case of structural steel when tests of samples have been made, when the load is entirely a steady one of a known amount, and there is no reason to fear the deterioration of the metal by corrosion, the lowest factor that should be adopted is 3.

2. When the circumstances of 1 are modified by a portion of the load being variable, as in floors of warehouses, the factor should be not less than 4.

3. When the whole load, or nearly the whole, is apt to be alternately put on and taken off, as in suspension rods of floors of bridges, the factor should be 5 or 6.

4. When the stresses are reversed in direction from tension to compression, as in some bridge diagonals and parts of machines, the factor should be not less than 6.

5. When the piece is subjected to repeated shocks, the factor should be not less than 10.

6. When the piece is subject to deterioration from corrosion the section should be sufficiently increased to allow for a definite amount of corrosion before the piece be so far weakened by it as to require removal.

7. When the strength of the material, or the amount of the load, or both are uncertain, the factor should be increased by an allowance sufficient to cover the amount of the uncertainty.

8. When the strains are of a complex character and of uncertain amount, such as those in the crank-shaft of a reversing engine, a very high factor is necessary, possibly even as high as 40, the figure given by Rankine for shafts in millwork.

### THE MECHANICAL PROPERTIES OF CORK.

Cork possesses qualities which distinguish it from all other solid or liquid bodies, namely, its power of altering its volume in a very marked degree in consequence of change of pressure. It consists, practically, of an aggregation of minute air-vessels, having thin, water-tight, and very strong walls, and hence, if compressed, the resistance to compression rises in a manner more like the resistance of gases than the resistance of an elastic solid such as a spring. In a spring the pressure increases in proportion to the distance to which the spring is compressed, but with gases the pressure increases in a much more rapid manner; that is, inversely as the volume which the gas is made to occupy. But from the permeability of cork to air, it is evident that, if subjected to pressure in one direction only, it will gradually part with its occluded air by effusion, that is, by its passage through the porous walls of the cells in which it is contained. The gaseous part of cork constitutes 53% of its bulk. Its elasticity has not only a very considerable range, but it is very persistent. Thus in the better kind of corks used in bottling the corks expand the instant they escape from the bottles. This expansion may amount to an increase of volume of 75%, even after the corks have been kept in a state of compression in the bottles for ten years. If the cork be steeped in hot water, the volume continues to increase till it attains nearly three times that which it occupied in the neck of the bottle.

When cork is subjected to pressure a certain amount of permanent deformation or "permanent set" takes place very quickly. This property is common to all solid elastic substances when strained beyond their elastic limits, but with cork the limits are comparatively low. Besides the permanent set, there is a certain amount of sluggish elasticity—that is, cork on being released from pressure springs back a certain amount at once, but the complete recovery takes an appreciable time.

Cork which had been compressed and released in water many thousand times had not changed its molecular structure in the least, and had continued perfectly serviceable. Cork which has been kept under a pressure of three atmospheres for many weeks appears to have shrunk to from 80% to 85% of its original volume.—*Van Nostrand's Eng'g Mag.* 1886, xxxv. 307.

### TESTS OF VULCANIZED INDIA-RUBBER.

Lieutenant L. Vladomiroff, a Russian naval officer, has recently carried out a series of tests at the St. Petersburg Technical Institute with a view to establishing rules for estimating the quality of vulcanized india-rubber. The following, in brief, are the conclusions arrived at, recourse being had to physical properties, since chemical analysis did not give any reliable result: 1. India-rubber should not give the least sign of superficial cracking when bent to an angle of 180 degrees after five hours of exposure in a closed air-bath to a temperature of 125° C. The test-pieces should be 2.4 inches thick. 2. Rubber that does not contain more than half its weight of metallic oxides should stretch to five times its length without breaking. 3. Rubber free from all foreign matter, except the sulphur used in vulcanizing it, should stretch to at least seven times its length without rupture. 4. The extension measured immediately after rupture should not exceed 12% of the original length, with given dimensions. 5. Suppleness may be determined by measuring the percentage of ash formed in incineration. This may form the basis for deciding between different grades of rubber for certain purposes. 6. Vulcanized rubber should not harden under cold. These rules have been adopted for the Russian navy.—*Iron Age*, June 15, 1893.

### XYLOLITH, OR WOODSTONE

is a material invented in 1883, but only lately introduced to the trade by Otto Serrig & Co., of Pottschappel, near Dresden. It is made of magnesia

cement, or calcined magnesite, mixed with sawdust and saturated with a solution of chloride of calcium. This pasty mass is spread out into sheets and submitted to a pressure of about 1000 lbs. to the square inch, and then simply dried in the air. Specific gravity 1.553. The fractured surface shows a uniform close grain of a yellow color. It has a tensional resistance when dry of 100 lbs. per square inch, and when wet about 66 lbs. When immersed in water for 12 hours it takes up 2.1% of its weight, and 3.8% when immersed 216 hours.

When treated for several days with hydrochloric acid it loses 2.3% in weight, and shows no loss of weight under boiling in water, brine, soda-lye, and solution of sulphates of iron, of copper, and of ammonium. In hardness the material stands between feldspar and quartz, and as a non-conductor of heat it ranks between asbestos and cork.

It stands fire well, and at a red heat it is rendered brittle and crumbles at the edges, but retains its general form and cohesion. This xylolith is supplied in sheets from  $\frac{1}{4}$  in. to  $1\frac{1}{2}$  in. thick, and up to one metre square. It is extensively used in Germany for floors in railway stations, hospitals, etc., and for decks of vessels. It can be sawed, bored, and shaped with ordinary woodworking tools. Putty in the joints and a good coat of paint make it entirely water-proof. It is sold in Germany for flooring at about 7 cents per square foot, and the cost of laying adds about 4 cents more.—*Eng'g News*, July 28, 1892, and July 27, 1893.

### ALUMINUM—ITS PROPERTIES AND USES.

(By Alfred E. Hunt, Pres't of the Pittsburgh Reduction Co.)

The specific gravity of pure aluminum in a cast state is 2.58; in rolled bars of large section it is 2.6; in very thin sheets subjected to high compression under chilled rolls, it is as much as 2.7. Taking the weight of a given bulk of cast aluminum as 1, wrought iron is 2.90 times heavier; structural steel, 2.95 times; copper, 3.60; ordinary high brass, 3.45. Most wood suitable for use in structures has about one third the weight of aluminum, which weighs 0.092 lb. to the cubic inch.

Pure aluminum is practically not acted upon by boiling water or steam. Carbonic oxide or hydrogen sulphide does not act upon it at any temperature under 600° F. It is not acted upon by most organic secretions.

Hydrochloric acid is the best solvent for aluminum, and strong solutions of caustic alkalies readily dissolve it. Ammonia has a slight solvent action, and concentrated sulphuric acid dissolves aluminum upon heating, with evolution of sulphurous acid gas. Dilute sulphuric acid acts but slowly on the metal, though the presence of any chlorides in the solution allow rapid decomposition. Nitric acid, either concentrated or dilute, has very little action upon the metal, and sulphur has no action unless the metal is at a red heat. Sea-water has very little effect on aluminum. Strips of the metal placed on the sides of a wooden ship corroded less than  $\frac{1}{1000}$  inch after six months' exposure to sea-water, corroding less than copper sheets similarly placed.

In malleability pure aluminum is only exceeded by gold and silver. In ductility it stands seventh in the series, being exceeded by gold, silver, platinum, iron, very soft steel, and copper. Sheets of aluminum have been rolled down to a thickness of 0.0005 inch, and beaten into leaf nearly as thin as gold leaf. The metal is most malleable at a temperature of between 400° and 600° F., and at this temperature it can be drawn down between rolls with nearly as much draught upon it as with heated steel. It has also been drawn down into the very finest wire. By the Mannesmann process aluminum tubes have been made in Germany.

Aluminum stands very high in the series as an electro-positive metal, and contact with other metals should be avoided, as it would establish a galvanic couple.

The electrical conductivity of aluminum is only surpassed by pure copper, silver, and gold. With silver taken at 100 the electrical conductivity of aluminum is 54.20; that of gold on the same scale is 78; zinc is 29.90; iron is only 16, and platinum 10.60. Pure aluminum has no polarity, and the metal in the market is absolutely non-magnetic.

Sound castings can be made of aluminum in either dry or "green" sand moulds, or in metal "chills." It must not be heated much beyond its melting-point, and must be poured with care, owing to the ready absorption of occluded gases and air. The shrinkage in cooling is  $\frac{17}{64}$  inch per foot, or a little more than ordinary brass. It should be melted in plumbago crucibles, and the metal becomes molten at a temperature of 1120° F. according to Professor Roberts-Austen, or at 1300° F. according to Richards.

The coefficient of linear expansion, as tested on  $\frac{3}{8}$ -inch round aluminum rods, is 0.00002295 per degree centigrade between the freezing and boiling point of water. The mean specific heat of aluminum is higher than that of any other metal, excepting only magnesium and the alkali metals. From zero to the melting-point it is 0.2185; water being taken as 1, and the latent heat of fusion at 28.5 heat units. The coefficient of thermal conductivity of unannealed aluminum is 37.96; of annealed aluminum, 38.37. As a conductor of heat aluminum ranks fourth, being exceeded only by silver, copper, and gold.

Aluminum, under tension, and section for section, is about as strong as cast iron. The tensile strength of aluminum is increased by cold rolling or cold forging, and there are alloys which add considerably to the tensile strength without increasing the specific gravity to over 3 or 3.25.

The strength of commercial aluminum is given in the following table as the result of many tests :

Form.	Elastic Limit per sq. in. in Tension, lbs.	Ultimate Strength per sq. in. in Tension, lbs.	Percentage of Reduct'n of Area in Tension.
Castings.....	6,500	15,000	15
Sheet.....	12,000	24,000	35
Wire.....	16,000-30,000	30,000-65,000	60
Bars.....	14,000	28,000	40

The elastic limit per square inch under compression in cylinders, with length twice the diameter, is 3500. The ultimate strength per square inch under compression in cylinders of same form is 12,000. The modulus of elasticity of cast aluminum is about 11,000,000. It is rather an open metal in its texture, and for cylinders to stand pressure an increase in thickness must be given to allow for this porosity. Its maximum shearing stress in castings is about 12,000, and in forgings about 16,000, or about that of pure copper.

Pure aluminum is too soft and lacking in tensile strength and rigidity for many purposes. Valuable alloys are now being made which seem to give great promise for the future. They are alloys containing from 2% to 7% or 8% of copper, manganese, iron, and nickel. As nickel is one of the principal constituents, these alloys have the trade name of "Nickel-aluminum."

Plates and bars of this nickel alloy have a tensile strength of from 40,000 to 50,000 pounds per square inch, an elastic limit of 55% to 60% of the ultimate tensile strength, an elongation of 20% in 2 inches, and a reduction of area of 25%.

This metal is especially capable of withstanding the punishment and distortion to which structural material is ordinarily subjected. Nickel-aluminum alloys have as much resilience and spring as the very hardest of hard-drawn brass.

Their specific gravity is about 2.80 to 2.85, where pure aluminum has a specific gravity of 2.72.

In castings, more of the hardening elements are necessary in order to give the maximum stiffness and rigidity, together with the strength and ductility of the metal; the favorite alloy material being zinc, iron, manganese, and copper. Tin added to the alloy reduces the shrinkage, and alloys of aluminum and tin can be made which have less shrinkage than cast iron.

The tensile strength of hardened aluminum-alloy castings is from 20,000 to 25,000 pounds per square inch.

Alloys of aluminum and copper form two series, both valuable. The first is aluminum-bronze, containing from 5% to 11½% of aluminum; and the second is copper-hardened aluminum, containing from 2% to 15% of copper. Aluminum-bronze is a very dense, fine-grained, and strong alloy, having good ductility as compared with tensile strength. The 10% bronze in forged bars will give 100,000 lbs. tensile strength per square inch, with 60,000 lbs. elastic limit per square inch, and 10% elongation in 8 inches. The 5% to 7½% bronze has a specific gravity of 8 to 8.30, as compared with 7.50 for the 10% to 11½% bronze, a tensile strength of 70,000 to 80,000 lbs., an elastic limit of 40,000 lbs. per square inch, and an elongation of 30% in 8 inches.

Aluminum is used by steel manufacturers to prevent the retention of the occluded gases in the steel, and thereby produce a solid ingot. The proportions of the dose range from ½ lb. to several pounds of aluminum per ton of steel. Aluminum is also used in giving extra fluidity to steel used in castings, making them sharper and sounder. Added to cast iron, aluminum causes the iron to be softer, free from shrinkage, and lessens the tendency to "chill."

With the exception of lead and mercury, aluminum unites with all metals,

though it unites with antimony with great difficulty. A small percentage of silver whitens and hardens the metal, and gives it added strength; and this alloy is especially applicable to the manufacture of fine instruments and apparatus. The following alloys have been found recently to be useful in the arts: Nickel-aluminum, composed of 20 parts nickel to 80 of aluminum; rosine, made of 40 parts nickel, 10 parts silver, 30 parts aluminum, and 20 parts tin, for jewellers' work; mettaline, made of 35 parts cobalt, 25 parts aluminum, 10 parts iron, and 30 parts copper. The aluminum-bourbounz metal, shown at the Paris Exposition of 1889, has a specific gravity of 2.9 to 2.96, and can be cast in very solid shapes, as it has very little shrinkage. From analysis the following composition is deduced: Aluminum, 85.74%; tin, 12.94%; silicon, 1.32%; iron, none.

The metal can be readily electrically welded, but soldering is still not satisfactory. The high heat conductivity of the aluminum withdraws the heat of the molten solder so rapidly that it "freezes" before it can flow sufficiently. A German solder said to give good results is made of 80% tin to 20% zinc, using a flux composed of 80 parts stearic acid, 10 parts chloride of zinc, and 10 parts of chloride of tin. Pure tin, fusing at 250° C., has also been used as a solder. The use of chloride of silver as a flux has been patented, and used with ordinary soft solder has given some success. A pure nickel soldering-bit should be used, as it does not discolor aluminum as copper bits do.

\* The tests of the alloys of copper and tin and of copper and zinc, the results of which are published in the Report of the U. S. Board appointed to test Iron, Steel, and other Metals, Vols. I and II, 1879 and 1881, were made by the author under direction of Prof. R. H. Thurston, chairman of the Committee on Alloys. See preface to the report of the Committee, in Vol. I.

Nos. 1a and 2 were full of blow-holes.

Tests Nos. 1 and 1a show the variation in cast copper due to varying conditions of casting. In the crushing tests Nos. 12 to 20, inclusive, crushed and broke under the strain, but all the others bulged and flattened out. In these cases the crushing strength is taken to be that which caused a decrease of 10% in the length. The test-pieces were 2 in. long and  $\frac{5}{8}$  in. diameter. The torsional tests were made in Thurston's torsion-machine, on pieces  $\frac{5}{8}$  in. diameter and 1 in. long between heads.

**Specific Gravity of the Copper-tin Alloys.**—The specific gravity of copper, as found in these tests, is 8.874 (tested in turnings from the ingot, and reduced to 39.1° F.). The alloy of maximum sp. gr. 8.956 contained 62.42 copper, 37.48 tin, and all the alloys containing less than 37% tin varied irregularly in sp. gr. between 8.65 and 8.93, the density depending not on the composition, but on the porosity of the casting. It is probable that the actual sp. gr. of all these alloys containing less than 37% tin is about 8.95, and any smaller figure indicates porosity in the specimen.

From 37% to 100% tin, the sp. gr. decreases regularly from the maximum of 8.956 to that of pure tin, 7.293.

### Note on the Strength of the Copper-tin Alloys.

The bars containing from 2% to 24% tin, inclusive, have considerable strength, and all the rest are practically worthless for purposes in which strength is required. The dividing line between the strong and brittle alloys is precisely that at which the color changes from golden yellow to silver-white, viz., at a composition containing between 24% and 30% of tin.

It appears that the tensile and compressive strengths of these alloys are in no way related to each other, that the torsional strength is closely proportional to the tensile strength, and that the transverse strength may depend in some degree upon the compressive strength, but it is much more nearly related to the tensile strength. The modulus of rupture, as obtained by the transverse tests, is, in general, a figure between those of tensile and compressive strengths per square inch, but there are a few exceptions in which it is larger than either.

The strengths of the alloys at the copper end of the series increase rapidly with the addition of tin till about 4% of tin is reached. The transverse strength continues regularly to increase to the maximum, till the alloy containing about 17 $\frac{1}{2}$ % of tin is reached, while the tensile and torsional strengths also increase, but irregularly, to the same point. This irregularity is probably due to porosity of the metal, and might possibly be removed by any means which would make the castings more compact. The maximum is reached at the alloy containing 82.70 copper, 17.34 tin, the transverse strength, however, being very much greater at this point than the tensile or torsional strength. From the point of maximum strength the figures drop rapidly to the alloys containing about 27.5% of tin, and then more slowly to 37.5%, at which point the minimum (or nearly the minimum) strength, by all three methods of test, is reached. The alloys of minimum strength are found from 37.5% tin to 52.5% tin. The absolute minimum is probably about 45% of tin.

From 52.5% of tin to about 77.5% tin there is a rather slow and irregular increase in strength. From 77.5% tin to the end of the series, or all tin, the strengths slowly and somewhat irregularly decrease.

The results of these tests do not seem to corroborate the theory given by some writers, that peculiar properties are possessed by the alloys which are compounded of simple multiples of their atomic weights or chemical equivalents, and that these properties are lost as the compositions vary more or less from this definite constitution. It does appear that a certain percentage composition gives a maximum strength and another certain percentage a minimum, but neither of these compositions is represented by simple multiples of the atomic weights.

There appears to be a regular law of decrease from the maximum to the minimum strength which does not seem to have any relation to the atomic proportions, but only to the percentage compositions.

**Hardness.**—The pieces containing less than 24% of tin were turned in the lathe without difficulty, a gradually increasing hardness being noticed, the last named giving a very short chip, and requiring frequent sharpening of the tool.

With the most brittle alloys it was found impossible to turn the test-pieces in the lathe to a smooth surface. No. 13 to No. 17 (26.85 to 34.47 tin) could not be cut with a tool at all. Chips would fly off in advance of the tool and

beneath it, leaving a rough surface; or the tool would sometimes, apparently, crush off portions of the metal, grinding it to powder. Beyond 40% tin the hardness decreased so that the bars could be easily turned.

**Variation in Strength of Gun-bronze, and Means of Improving the Strength.**—The figures obtained for alloys of from 7.8% to 12.7% tin, viz., from 26,860 to 29,430 pounds, are much less than are usually given as the strength of gun-metal. Bronze guns are usually cast under the pressure of a head of metal, which tends to increase the strength and density. The strength of the upper part of a gun casting, or sinking head, is not greater than that of the small bars which have been tested in these experiments. The following is an extract from the report of Major Wade concerning the strength and density of gun-bronze (1850):—Extreme variation of six samples from different parts of the same gun (a 32-pounder howitzer): Specific gravity, 8.487 to 8.835; tenacity, 26,428 to 52,192. Extreme variation of all the samples tested: Specific gravity, 8.308 to 8.850; tenacity, 23,108 to 54,531. Extreme variation of all the samples from the gun heads: Specific gravity, 8.308 to 8.756; tenacity, 23,529 to 35,484.

Major Wade says: The general results on the quality of bronze as it is found in guns are mostly of a negative character. They expose defects in density and strength, develop the heterogeneous texture of the metal in different parts of the same gun, and show the irregularity and uncertainty of quality which attend the casting of all guns, although made from similar materials, treated in like manner.

Navy ordnance bronze containing 9 parts copper and 1 part tin, tested at Washington, D. C., in 1875-6, showed a variation in tensile strength from 29,800 to 51,400 lbs. per square inch, in elongation from 3% to 58%, and in specific gravity from 8.39 to 8.88.

That a great improvement may be made in the density and tenacity of gun-bronze by compression has been shown by the experiments of Mr. S. B. Dean in Boston, Mass., in 1869, and by those of General Uchatius in Austria in 1873. The former increased the density of the metal next the bore of the gun from 8.321 to 8.875, and the tenacity from 27,238 to 41,471 pounds per

square inch. The latter, by a similar process, obtained the following figures for tenacity:

	Pounds per sq. in.
Bronze with 10% tin.....	72,053
Bronze with 8% tin.....	73,958
Bronze with 6% tin.....	77,656

The transverse tests were made in bars 1 in. square, 22 in. between supports. The tensile tests were made on bars 0.798 in. diam. turned from the two halves of the transverse-test bar, one half being marked A and the other B.

**Ancient Bronzes.**—The usual composition of ancient bronze was the same as that of modern gun-metal—90 copper, 10 tin; but the proportion of tin varies from 5% to 15%, and in some cases lead has been found. Some ancient Egyptian tools contained 88 copper, 12 tin.

**Strength of the Copper-zinc Alloys.**—The alloys containing less than 15% of zinc by original mixture were generally defective. The bars were full of blow-holes, and the metal showed signs of oxidation. To insure good castings it appears that copper-zinc alloys should contain more than 15% of zinc.

From No. 2 to No. 8 inclusive, 16.98 to 30.06% zinc the bars show a remarkable similarity in all their properties. They have all nearly the same strength and ductility, the latter decreasing slightly as zinc increases, and are nearly alike in color and appearance. Between Nos. 8 and 10, 30.06 and 36.36% zinc, the strength by all methods of test rapidly increases. Between No. 10 and No. 15, 36.36 and 50.14% zinc, there is another group, distinguished by high strength and diminished ductility. The alloy of maximum tensile, transverse and torsional strength contains about 41% of zinc.

The alloys containing less than 55% of zinc are all yellow metals. Beyond 55% the color changes to white, and the alloy becomes weak and brittle. Between 70% and pure zinc the color is bluish gray, the brittleness decreases and the strength increases, but not to such a degree as to make them useful for constructive purposes.

**Difference between Composition by Mixture and by Analysis.**—There is in every case a smaller percentage of zinc in the average analysis than in the original mixture, and a larger percentage of copper. The loss of zinc is variable, but in general averages from 1 to 2%.

**Liquation or Separation of the Metals.**—In several of the bars a considerable amount of liquation took place, analysis showing a difference in composition of the two ends of the bar. In such cases the change in composition was gradual from one end of the bar to the other, the upper end in general containing the higher percentage of copper. A notable instance was bar No. 13, in the above table, turnings from the upper end containing 40.36% of zinc, and from the lower end 48.52%.

**Specific Gravity.**—The specific gravity follows a definite law, varying with the composition, and decreasing with the addition of zinc. From the plotted curve of specific gravities the following mean values are taken:

Per cent zinc.....	0	10	20	30	40	50	60	70	80	90	100.
Specific gravity.....	8.80	8.72	8.60	8.40	8.36	8.20	8.00	7.72	7.40	7.20	7.14.

**Graphic Representation of the Law of Variation of Strength of Copper-Tin-Zinc Alloys.**—In an equilateral triangle the sum of the perpendicular distances from any point within it to the three sides is equal to the altitude. Such a triangle can therefore be used to show graphically the percentage composition of any compound of three parts, such as a triple alloy. Let one side represent 0 copper, a second 0 tin, and the third 0 zinc, the vertex opposite each of these sides representing 100 of each element respectively. On points in a triangle of wood representing different alloys tested, wires were erected of lengths proportional to the tensile strengths, and the triangle then built up with plaster to the height of the wires. The surface thus formed has a characteristic topography representing the variations of strength with variations of composition. The cut shows the surface thus made. The vertical section to the left represents the law of tensile strength of the copper-tin alloys, the one to the right that of tin-zinc alloys, and the one at the rear that of the copper-zinc alloys. The high point represents the strongest possible alloys of the three metals. Its composition is copper 55, zinc 43, tin 2, and its strength about 70,000 lbs. The high ridge from this point to the point of maximum height of the section on the left is the line of the strongest alloys, represented by the formula  $\text{zinc} + (3 \times \text{tin}) = 55$ .

All alloys lying to the rear of the ridge, containing more copper and less tin or zinc are alloys of greater ductility than those on the line of maximum strength, and are the valuable commercial alloys; those in front on the declivity toward the central valley are brittle, and those in the valley are both brittle and weak. Passing from the valley toward the section at the right the alloys lose their brittleness and become soft, the maximum softness being at tin = 100, but they remain weak, as is shown by the low elevation of the surface. This model was planned and constructed by Prof. Thurston in 1877. (See Trans. A. S. C. E. 1881 Report of the U. S. Board appointed to

test Iron, Steel, etc., vol. II., Washington, 1881, and Thurston's *Materials of Engineering*, vol. III.)

The best alloy obtained in Thurston's research for the U. S. Testing Board has the composition, Copper 55, Tin 0.5, Zinc 44.5. The tensile strength in a cast bar was 68,900 lbs. per sq. in., two specimens giving the same result; the elongation was 47 to 51 per cent in 5 inches. Thurston's formula for copper-tin-zinc alloys of maximum strength (Trans. A. S. C. E., 1881) is  $z + 3t = 55$ ,

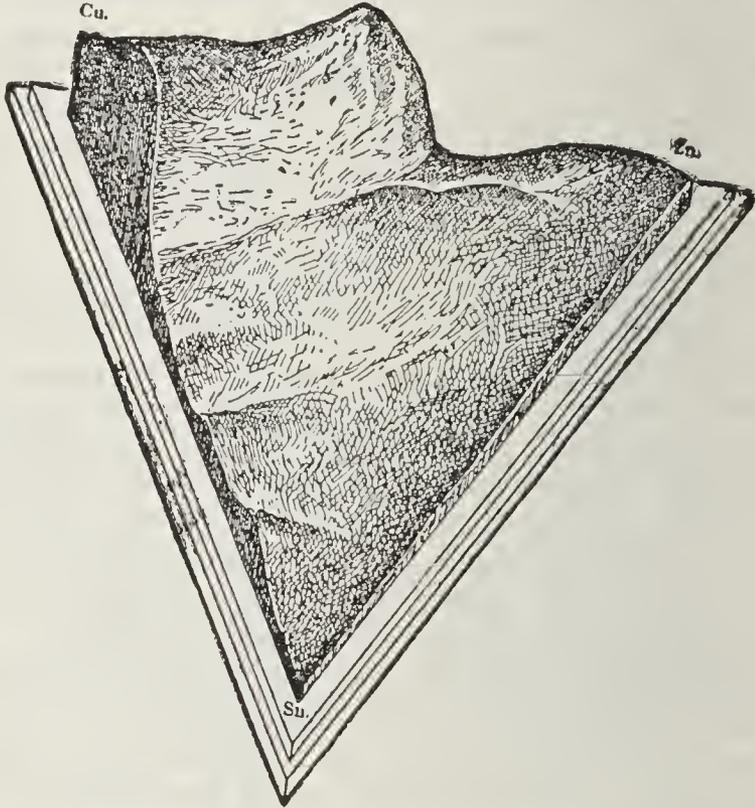

FIG. 77.

in which  $z$  is the percentage of zinc and  $t$  that of tin. Alloys proportioned according to this formula should have a strength of about 40,000 lbs. per sq. in.  $+ 500z$ . The formula fails with alloys containing less than 1 per cent of tin.

The following would be the percentage composition of a number of alloys made according to this formula, and their corresponding tensile strength in castings:

Tin.	Zinc.	Copper.	Tensile Strength, lbs. per sq. in.	Tin.	Zinc.	Copper.	Tensile Strength, lbs. per sq. in.
1	52	47	66,000	8	31	61	55,500
2	49	49	64,500	9	28	63	54,000
3	46	51	63,000	10	25	65	52,500
4	43	53	61,500	12	19	69	49,500
5	40	55	60,000	14	13	73	46,500
6	37	57	58,500	16	7	77	43,500
7	34	59	57,000	18	1	81	40,500

These alloys, while possessing maximum tensile strength, would in general be too hard for easy working by machine tools. Another series made on the formula  $z + 4t = 50$  would have greater ductility, together with considerable strength, as follows, the strength being calculated as before, tensile strength in lbs. per sq. in. =  $40,000 + 500z$ .

Tin.	Zinc.	Copper.	Tensile Strength, lbs. per sq. in.	Tin.	Zinc.	Copper.	Tensile Strength, lbs. per sq. in.
1	46	53	63,000	7	22	71	51,000

**Tobin Bronze.**—This alloy is practically a *sterro* or *delta* metal with the addition of a small amount of lead, which tends to render copper softer and more ductile. (F. L. Garrison, *J. F. I.*, 1891.)

The following analyses of Tobin bronze were made by Dr. Chas. B. Dudley:

	Pig Metal, per cent.	Test Bar (Rolled), per cent.
Copper.....	59.00	61.20
Zinc....	38.40	37.14
Tin.....	2.16	0.90
Iron.....	0.11	0.18
Lead.....	0.31	0.35

Dr. Dudley writes, “We tested the test bars and found 78,500 tensile strength with 15% elongation in two inches, and 40½% in eight inches. This high tensile strength can only be obtained when the metal is manipulated. Such high results could hardly be expected with cast metal.”

The original Tobin bronze in 1875, as described by Thurston, *Trans. A. S. C. E.* 1881, had, composition of copper 58.22, tin 2.30, zinc 39.48. As cast it had a tenacity of 66,000 lbs. per sq. in., and as rolled 79,000 lbs.; cold rolled it gave 104,000 lbs.

A circular of Ansonia Brass & Copper Co. gives the following:—The tensile strength of six Tobin bronze one-inch round rolled rods, turned down to a diameter of ⅝ of an inch, tested by Fairbanks, averaged 79,600 lbs. per sq. in., and the elastic limit obtained on three specimens averaged 54,257 lbs. per sq. in.

At a cherry-red heat Tobin bronze can be forged and stamped as readily as steel. Bolts and nuts can be forged from it, either by hand or by machinery, with a marked degree of economy. Its great tensile strength, and resistance to the corrosive action of sea-water, render it a most suitable metal for condenser plates, steam-launch shafting, ship sheathing and fastenings, nails, hull plates for steam yachts, torpedo and life boats, and ship deck fittings.

The Navy Department has specified its use for certain purposes in the machinery of the new cruisers. Its specific gravity is 8.071. The weight of a cubic inch is .291 lb.

Copper 91.4      Tin 5.7      Lead 2.9      Very fusible.

### COPELAND-ZINC-IRON ALLOYS.

(F. L. Garrison, *Jour. Frank. Inst.*, June and July, 1891.)

**Delta Metal.**—This alloy, which was formerly known as *sterro-metal*, is composed of about 60 copper, from 34 to 44 zinc, 2 to 4 iron, and 1 to 2 tin.

The peculiarity of all these alloys is the content of iron, which appears to have the property of increasing their strength to an unusual degree. In making delta metal the iron is previously alloyed with zinc in known and definite proportions. When ordinary wrought-iron is introduced into molten zinc, the latter readily dissolves or absorbs the former, and will take

it up to the extent of about 5% or more. By adding the zinc-iron alloy thus obtained to the requisite amount of copper, it is possible to introduce any definite quantity of iron up to 5% into the copper alloy. Garrison gives the following as the range of composition of copper-zinc-iron, and copper-zinc-tin-iron alloys:

I.		II.	
	Per cent.		Per cent.
Iron.....	0.1 to 5	Iron.....	0.1 to 5
Copper ...	50 to 65	Tin.....	0.1 to 10
Zinc .....	49.9 to 30	Zinc.....	1.8 to 45
		Copper.....	98 to 40

The advantages claimed for delta metal are great strength and toughness. It produces sound castings of close grain. It can be rolled and forged hot, and can stand a certain amount of drawing and hammering when cold. It takes a high polish, and when exposed to the atmosphere tarnishes less than brass.

When cast in sand delta metal has a tensile strength of about 45,000 pounds per square inch, and about 10% elongation; when rolled, tensile strength of 60,000 to 75,000 pounds per square inch, elongation from 9% to 17% on bars 1.128 inch in diameter and 1 inch area.

Wallace gives the ultimate tensile strength 33,600 to 51,520 pounds per square inch, with from 10% to 20% elongation.

Delta metal can be forged, stamped and rolled hot. It must be forged at a dark cherry-red heat, and care taken to avoid striking when at a black heat.

According to Lloyd's Proving House tests, made at Cardiff, December 20, 1887, a half-inch delta metal-rolled bar gave a tensile strength of 88,400 pounds per square inch, with an elongation of 30% in three inches.

### PHOSPHOR-BRONZE AND OTHER SPECIAL BRONZES.

**Phosphor-bronze.**—In the year 1868, Montefiore & Kunzel of Liège, Belgium, found by adding small proportions of phosphorus or "phosphoret of tin or copper" to copper that the oxides of that metal, nearly always present as an impurity, more or less, were deoxidized and the copper much improved in strength and ductility, the grain of the fracture became finer, the color brighter, and a greater fluidity was attained.

Three samples of phosphor-bronze tested by Kirkaldy gave:

Elastic limit, lbs. per sq. in. ....	23,800	24,700	16,100
Tensile strength, lbs. per sq. in. ...	52,625	46,100	44,448
Elongation, per cent.....	8.40	1.50	33.40

The strength of phosphor-bronze varies like that of ordinary bronze according to the percentages of copper, tin, zinc, lead, etc., in the alloy.

**Deoxidized Bronze.**—This alloy resembles phosphor bronze somewhat in composition and also delta metal, in containing zinc and iron. The following analysis gives its average composition:

Copper.....	82.67	Iron.....	0.10
Tin.....	12.40	Silver.....	0.07
Zinc.....	3.23	Phosphorus.....	0.005
Lead.....	2.14		
			100.615

### Comparison of Copper, Silicon-bronze, and Phosphor-bronze Wires. (Engineering, Nov. 23, 1883.)

Description of Wire.	Tensile Strength.	Relative Conductivity.
Pure copper.....	39,827 lbs. per sq. in.	100 per cent.
Silicon bronze (telegraph)....	41,696 " " " "	96 " "
" " (telephone)....	108,080 " " " "	34 " "
Phosphor bronze (telephone)..	102,390 " " " "	26 " "

**Penn. R. R. Co.'s Specifications for Phosphor-Bronze (1902).**—The metal desired is homogeneous alloy of copper, 79.70; tin, 10.00; lead, 9.50; phosphorus, 0.80. Lots will not be accepted if samples do not show tin, between 9 and 11%; lead, between 8 and 11%; phosphorus, between 0.7 and 1%; nor if the metal contains a sum total of other substances than copper, tin, lead, and phosphorus in greater quantity than 0.50 per cent. (See also p. 334.)

**Silicon Bronze.** (*Aluminum World*, May, 1897.)

The most useful of the silicon bronzes are the 3% (97% copper, 3% silicon) and the 5% (95% copper, 5% silicon), although the hardness and strength of the alloy can be increased or decreased at will by increasing or decreasing silicon. A 3% silicon bronze has a tensile strength, in a casting, of about 55,000 lbs. per sq. in., and from 50% to 60% elongation. The 5% bronze has a tensile strength of about 75,000 lbs. and about 8% elongation. More than 5% or 5½% of silicon in copper makes a brittle alloy. In using silicon, either as a flux or for making silicon bronze, the rich alloy of silicon and copper which is now on the market should be used. It should be free from iron and other metals if the best results are to be obtained. Ferro-silicon is not suitable for use in copper or bronze mixtures.

**ALUMINUM ALLOYS.**

**Aluminum Bronze.** (Cowles Electric Smelting and Al. Co.'s circular.)

The standard A No. 2 grade of aluminum bronze, containing 10% of aluminum and 90% of copper, has many remarkable characteristics which distinguish it from all other metals.

The tenacity of castings of A No. 2 grade metal varies between 75,000 and 90,000 lbs. to the square inch, with from 4% to 14% elongation.

Increasing the proportion of aluminum in bronze beyond 11% produces a brittle alloy; therefore nothing higher than the A No. 1, which contains 11%, is made.

The B, C, D, and E grades, containing 7½%, 5%, 2½%, and 1¼% of aluminum, respectively, decrease in tenacity in the order named, that of the former being about 65,000 pounds, while the latter is 25,000 pounds. While there is also a proportionate decrease in transverse and torsional strengths, elastic limit, and resistance to compression as the percentage of aluminum is lowered and that of copper raised, the ductility on the other hand increases in the same proportion. The specific gravity of the A No. 1 grade is 7.56.

Bell Bros., Newcastle, gave the specific gravity of the aluminum bronzes as follows:

3%, 8.691; 4%, 8.621; 5%, 8.369; 10%, 7.689.

**Tests of Aluminum Bronzes.**

(By John H. J. Dagger, in a paper read before the British Association, 1889.)

Per cent of Aluminum.	Tensile Strength.		Elongation, per cent.	Specific Gravity.
	Tons per square inch.	Pounds per square inch.		
11.....	40 to 45	89,600 to 100,800	8	7.23
10.....	33 " 40	73,920 " 89,600	14	7.69
7½.....	25 " 30	56,000 " 67,200	40	8.00
5-5½.....	15 " 18	33,600 " 40,320	40	8.37
2½.....	13 " 15	29,120 " 33,600	50	8.69
1¼.....	11 " 13	24,640 " 29,120	55	...

Both physical and chemical tests made of samples cut from various sections of 2½%, 5%, 7½%, or 10% aluminumized copper castings tend to prove that the aluminum unites itself with each particle of copper with uniform proportion in each case, so that we have a product that is free from liquation and highly homogeneous. (R. C. Cole, *Iron Age*, Jan. 16, 1890.)

**Casting.**—The melting point of aluminum bronze varies slightly with the amount of aluminum contained, the higher grades melting at a somewhat lower temperature than the lower grades. The A No. 1 grades melt at about 1700° F., a little higher than ordinary bronze or brass.

Aluminum bronze shrinks more than ordinary brass. As the metal solidifies rapidly it is necessary to pour it quickly and to make the feeders amply large, so that there will be no "freezing" in them before the casting is properly fed. Baked-sand moulds are preferable to green sand, except for small castings, and when fine skin colors are desired in the castings. (See paper by Thos. D. West, *Trans. A. S. M. E.* 1886, vol. viii.)

All grades of aluminum bronze can be rolled, swedged, spun, or drawn cold except A 1 and A 2. They can all be worked at a bright red heat.

In rolling, swedging, or spinning cold, it should be annealed very often, and at a brighter red heat than is used for annealing brass.

**Brazing.**—Aluminum bronze will braze as well as any other metal, using one quarter brass solder (zinc 500, copper 500 (and three quarters borax, or, better, three quarters cryolite.

**Soldering.**—To solder aluminum bronze with ordinary soft (pewter) solder: Cleanse well the parts to be joined free from grease and dirt. Then place the parts to be soldered in a strong solution of sulphate of copper and place in the bath a rod of soft iron touching the parts to be joined. After a while a coppery-like surface will be seen on the metal. Remove from bath, rinse quite clean, and brighten the surfaces. These surfaces can then be tinned by using a fluid consisting of zinc dissolved in hydrochloric acid, in the ordinary way, with common soft solder.

Mierzinski recommends ordinary hard solder, and says that Hnlot uses an alloy of the usual half-and-half lead-tin solder, with 12.5%, 25% or 50% of zinc amalgam.

**Aluminum-Brass** (E. H. Cowles, Trans. A. I. M. E., vol. xviii.)—Cowles aluminum-brass is made by fusing together equal weights of A 1 aluminum-bronze, copper, and zinc. The copper and bronze are first thoroughly melted and mixed, and the zinc is finally added. The material is left in the furnace until small test-bars are taken from it and broken. When these bars show a tensile strength of 80,000 pounds or over, with 2 or 3 per cent ductility, the metal is ready to be poured. Tests of this brass, on small bars, have at times shown as high as 100,000 pounds tensile strength.

The screw of the United States gunboat Petrel is cast from this brass, mixed with a trifle less zinc in order to increase its ductility.

**Tests of Aluminum-Brass.**

(Cowles E. S. & Al. Co.)

Specimen (Castings.)	Diameter of Piece, Inch.	Area, sq. in.	Tensile Strength, lbs. per sq. in.	Elastic Limit, lbs. per sq. in.	Elongation, per ct.	Remarks.
15% A grade Bronze. } 17% Zinc..... } 68% Copper..... }	.465	.1698	41,225	17,668	41½	These test pieces were all 6' long between the shoulders.
1 part A Bronze.... } 1 part Zinc..... } 1 part Copper.. .... }	.465	.1698	78,327	.....	2½	
1 part A Bronze.... } 1 part Zinc.... } 1 part Copper.... }	.460	.1661	72,246	.....	2½	

The first brass on the above list is an extremely tough metal with low elastic limit, made purposely so as to "upset" easily. The other, which is called Aluminum-brass No. 2, is very hard.

We have not in this country or in England any official standard by which to judge of the physical characteristics of cast metals. There are two conditions that are absolutely necessary to be known before we can make a fair comparison of different materials: namely, whether the casting was made in dry or green sand or in a chill, and whether it was attached to a larger casting or cast by itself. It has also been found that chill-castings give higher results than sand-castings, and that bars cast by themselves purposely for testing almost invariably run higher than test-bars attached to castings. It is also a fact that bars cut out from castings are generally weaker than bars cast alone. (E. H. Cowles.)

**Caution as to Reported Strength of Alloys.**—The same variation in strength which has been found in tests of gun-metal (copper and tin) noted above, must be expected in tests of aluminum bronze and in fact of all alloys. They are exceedingly subject to variation in density and in grain, caused by differences in method of molding and casting, temperature of pouring, size and shape of casting, depth of "sinking head," etc.

**Aluminum Hardened by Addition of Copper.**

Rolled Sheets .04 inch thick. (*The Engineer*, Jan. 2, 1891.)

Al. Per cent.	Cu. Per cent.	Sp. Gr. Calculated.	Sp. Gr. Determined.	Tensile Strength in pounds per square inch.

92.00	6.50	0.50	.....	.....	46,530	17,000	7.8	19.19

For comparison with the above 6 tests of "Navy Yard Bronze," Cu 88, Sn 10, Zn 2, are given in which the T. S. ranges from 18,000 to 24,590, E. L. from 10,000 to 13,000, El. 2.5 to 5.8%, Red. 4.7 to 10.89.

**Alloys of Aluminum, Silicon and Iron.**

M. and E. Bernard have succeeded in obtaining through electrolysis, by treating directly and without previous purification, the aluminum earths (red and white bauxites) the following :

Alloys such as ferro-aluminum, ferro-silicon-aluminum and silicon-aluminum, where the proportion of silicon may exceed 10% which are employed in the metallurgy of iron for refining steel and cast-iron.

Also silicon-aluminum, where the proportion of silicon does not exceed 10%, which may be employed in mechanical constructions in a rolled or hammered condition, in place of steel, on account of their great resistance, especially where the lightness of the piece in construction constitutes one of the main conditions of success.

The following analyses are given:

1. Alloys applied to the metallurgy of iron, the refining of steel and cast iron: No. 1. Al, 70%; Fe, 25%; Si, 5%. No. 2. Al, 70; Fe, 20; Si, 10. No. 3. Al, 70; Fe, 15; Si, 15. No. 4. Al, 70; Fe, 10; Si, 20. No. 5. Al, 70; Fe, 10; Si, 10; Mn, 10. No. 6. Al, 70; Fe, trace; Si, 20; Mn, 10.

2. Mechanical alloys: No. 1. Al, 92; Si, 6.75; Fe, 1.25. No. 2. Al, 90; Si, 9.25; Fe, 0.75. No. 3. Al, 90; Si, 10; Fe, trace. The best results were with alloys where the proportion of iron was very low, and the proportion of silicon in the neighborhood of 10%. Above that proportion the alloy becomes crystalline and can no longer be employed. The density of the alloys of silicon is approximately the same as that of aluminum.—*La Metallurgie*, 1892.

**Tungsten and Aluminum.**—Mr. Leinhardt Mannesmann says that the addition of a little tungsten to pure aluminum or its alloys communicates a remarkable resistance to the action of cold and hot water, salt water and other reagents. When the proportion of tungsten is sufficient the alloys offer great resistance to tensile strains.

**Aluminum, Copper, and Tin.**—Prof. R. C. Carpenter, Trans. A. S. M. E., vol. xix., finds the following alloys of maximum strength in a series in which two of the three metals are in equal proportions:

Al, 85; Cu, 7.5; Sn, 7.5; tensile strength, 33,000 lbs. per sq. in.; elongation in 6 in, 4%; sp. gr., 3.02. Al, 6.25; Cu, 87.5; Sn, 6.25; T. S., 63,000; El., 3.8; sp. gr., 7.35. Al, 5; Cu, 5; Sn, 90; T. S., 11,000; El., 10.1; sp. gr., 6.82.

**Aluminum and Zinc.**—Prof. Carpenter finds that the strongest alloy of these metals consists of two parts of aluminum and one part of zinc. Its tensile strength is 24,000 to 26,000 lbs. per sq. in.; has but little ductility, is readily cut with machine-tools, and is a good substitute for hard cast brass.

**Aluminum and Tin.**—M. Bourbouze has compounded an alloy of aluminum and tin, by fusing together 100 parts of the former with 10 parts of the latter. This alloy is paler than aluminum, and has a specific gravity of 2.85. The alloy is not as easily attacked by several reagents as alumi-

num is, and it can also be worked more readily. Another advantage is that it can be soldered as easily as bronze, without further preliminary preparations.

**Aluminum-Antimony Alloys.**—Dr. C. R. Alder Wright describes some aluminum-antimony alloys in a communication read before the Society of Chemical Industry. The results of his researches do not disclose the existence of a commercially useful alloy of these two metals, and have greater scientific than practical interest. A remarkable point is that the alloy with the chemical composition  $Al Sb$  has a higher melting point than either aluminum or antimony alone, and that when aluminum is added to pure antimony the melting-point goes up from that of antimony ( $450^{\circ} C.$ ) to a certain temperature rather above that of silver ( $1000^{\circ} C.$ ).

### ALLOYS OF MANGANESE AND COPPER.

**Various Manganese Alloys.**—E. H. Cowles, in *Trans. A. I. M. E.*, vol. xviii, p. 495, states that as the result of numerous experiments on mixtures of the several metals, copper, zinc, tin, lead, aluminum, iron, and manganese, and the metalloid silicon, and experiments upon the same in ascertaining tensile strength, ductility, color, etc., the most important determinations appear to be about as follows:

1. That pure metallic manganese exerts a bleaching effect upon copper more radical in its action even than nickel. In other words, it was found that  $18\frac{1}{2}\%$  of manganese present in copper produces as white a color in the resulting alloy as 25% of nickel would do, this being the amount of each required to remove the last trace of red.

2. That upwards of 20% or 25% of manganese may be added to copper without reducing its ductility, although doubling its tensile strength and changing its color.

3. That manganese, copper, and zinc when melted together and poured into moulds behave very much like the most "yeasty" German silver, producing an ingot which is a mass of blow-holes, and which swells up above the mould before cooling.

4. That the alloy of manganese and copper by itself is very easily oxidized.

5. That the addition of 1.25% of aluminum to a manganese-copper alloy converts it from one of the most refractory of metals in the casting process into a metal of superior casting qualities, and the non-corrodibility of which is in many instances greater than that of either German or nickel silver.

A "silver-bronze" alloy especially designed for rods, sheets, and wire has the following composition: Manganese, 18; aluminum, 1.20; silicon, 0.5; zinc, 13; and copper, 67.5%. It has a tensile strength of about 57,000 pounds on small bars, and 20% elongation. It has been rolled into thin plate and drawn into wire .008 inch in diameter. A test of the electrical conductivity of this wire (of size No. 33) shows its resistance to be 41.44 times that of pure copper. This is far lower conductivity than that of German silver.

**Manganese Bronze.** (F. L. Garrison, *Jour. F. I.*, 1891.)—This alloy has been used extensively for casting propeller-blades. Tests of some made by B. H. Cramp & Co., of Philadelphia, gave an average elastic limit of 30,000 pounds per square inch, tensile strength of about 60,000 pounds per square inch, with an elongation of 8% to 10% in sand castings. When rolled, the elastic limit is about 80,000 pounds per square inch, tensile strength 95,000 to 106,000 pounds per square inch, with an elongation of 12% to 15%.

Compression tests made at United States Navy Department from the metal in the pouring-gate of propeller-hub of U. S. S. *Maine* gave in two tests a crushing stress of 126,450 and 135,750 lbs. per sq. in. The specimens were 1 inch high by  $0.7 \times 0.7$  inch in cross-section = 0.49 square inch. Both specimens gave way by shearing, on a plane making an angle of nearly  $45^{\circ}$  with the direction of stress.

A test on a specimen  $1 \times 1 \times 1$  inch was made from a piece of the same pouring-gate. Under stress of 150,000 pounds it was flattened to 0.72 inch high by about  $1\frac{1}{4} \times 1\frac{1}{4}$  inches, but without rupture or any sign of distress.

One of the great objections to the use of manganese bronze, or in fact any alloy except iron or steel, for the propellers of iron ships is on account of the galvanic action set up between the propeller and the stern-posts. This difficulty has in great measure been overcome by putting strips of rolled zinc around the propeller apertures in the stern-frames.

The following analysis of Parsons' manganese bronze No. 2 was made from a chip from the propeller of Mr. W. K. Vanderbilt's yacht *Alva*.

Copper.....	88.644
Zinc .....	1.570
Tin .....	8.700
Iron.....	0.720
Lead .....	0.295
Phosphorus.....	trace
	99.929

It will be observed there is no manganese present and the amount of zinc is very small.

E. H. Cowles, Trans. A. I. M. E., vol. xviii, says: Manganese bronze, so called, is in reality a manganese brass, for zinc instead of tin is the chief element added to the copper. Mr. P. M. Parsons, the proprietor of this brand of metal, has claimed for it a tensile strength of from 24 to 28 tons on small bars when cast in sand. Mr. W. C. Wallace states that brass-founders of high repute in England will not admit that manganese bronze has more than from 12 to 17 tons tensile strength. Mr. Horace See found tensile strength of 45,000 pounds, and from 6% to 12½% elongation.

### GERMAN-SILVER AND OTHER NICKEL ALLOYS.

**German Silver.**—The composition of German silver is a very uncertain thing and depends largely on the honesty of the manufacturer and the price the purchaser is willing to pay. It is composed of copper, zinc, and nickel in varying proportions. The best varieties contain from 18% to 25% of nickel and from 20% to 30% of zinc, the remainder being copper. The more expensive nickel silver contains from 25% to 33% of nickel and from 75% to 66% of copper. The nickel is used as a whitening element; it also strengthens the alloy and renders it harder and more non-corrodible than the brass made without it, of copper and zinc. Of all troublesome alloys to handle in the foundry or rolling-mill, German silver is the worst. It is unmanageable and refractory at every step in its transition from the crude elements into rods, sheets, or wire. (E. H. Cowles, Trans. A. I. M. E., vol. xviii, p. 494.)

	Copper.	Nickel.	Tin.	Zinc.
German silver.....	51.6	25.8	22.6	.....
“ “ .....	50.2	14.8	3.1	31.9
“ “ .....	51.1	13.8	3.2	31.9
“ “ .....	52 to 55	18 to 25	.....	20 to 30
Nickel “ .....	75 to 66	25 to 33	.....	.....

A refined copper-nickel alloy containing 50% copper and 49% nickel, with very small amounts of iron, silicon and carbon, is produced direct from Bessemer matte in the Sudbury (Canada) Nickel Works. German silver manufacturers purchase a ready-made alloy, which melts at a low heat and requires simple addition of zinc, instead of buying the nickel and copper separately. This alloy, “50-50” as it is called, is almost indistinguishable from pure nickel. Its cost is less than nickel, its melting point much lower, it can be cast solid in any form desired, and furnishes a casting which works easily in the lathe or planer, yielding a silvery white surface unchanged by air or moisture. For bullet casings now used in various British and continental rifles, a special alloy of 80% copper and 20% nickel is made.

### ALLOYS OF BISMUTH.

By adding a small amount of bismuth to lead that metal may be hardened and toughened. An alloy consisting of three parts of lead and two of bismuth has ten times the hardness and twenty times the tenacity of lead. The alloys of bismuth with both tin and lead are extremely fusible, and take fine impressions of casts and moulds. An alloy of one part bismuth, two parts tin, and one part lead is used by pewter-workers as a soft solder, and by soap-makers for moulds. An alloy of five parts bismuth, two parts tin, and three parts lead melts at 199° F., and is somewhat used for stereotyping, and for metallic writing-pencils. Thorpe gives the following proportions for the better-known fusible metals:

Name of Alloy.	Bismuth.	Lead.	Tin.	Cad- mium	Mer- cury.	Melting- point.
Newton's.....	50	31.25	18.75	.....	.....	202° F.
Rose's.....	50	28.10	24.10	.....	.....	203° "
D'Arcet's.....	50	25.00	25.00	.....	.....	201° "
D'Arcet's with mercury.	50	25.00	25.00	.....	250.0	113° "
Wood's.....	50	25.00	12.50	12.50	.....	149° "
Lipowitz's.....	50	26.90	12.78	10.40	.....	149° "
Guthrie's "Entectic"...	50	20.55	21.10	14.03	.....	"Very low."

The action of heat upon some of these alloys is remarkable. Thus, Lipowitz's alloy, which solidifies at 149° Fah., contracts very rapidly at first, as it cools from this point. As the cooling goes on the contraction becomes slower and slower, until the temperature falls to 101.3° Fah. From this point the alloy *expands* as it cools, until the temperature falls to about 77° Fah., after which it again contracts, so that at 32° F. a bar of the alloy has the same length as at 115° F.

Alloys of bismuth have been used for making fusible plugs for boilers, but it is found that they are altered by the continued action of heat, so that one cannot rely upon them to melt at the proper temperature. Pure Banca tin is used by the U. S. Government for fusible plugs.

#### BEARING-METAL ALLOYS.

(C. B. Dudley, *Jour. F. I.*, Feb. and March, 1892.)

Alloys are used as bearings in place of wrought iron, cast iron, or steel, partly because wear and friction are believed to be more rapid when two metals of the same kind work together, partly because the soft metals are more easily worked and got into proper shape, and partly because it is desirable to use a soft metal which will take the wear rather than a hard metal, which will wear the journal more rapidly.

A good bearing-metal must have five characteristics: (1) It must be strong enough to carry the load without distortion. Pressures on car-journals are frequently as high as 350 to 400 lbs. per square inch.

(2) A good bearing-metal should not heat readily. The old copper-tin bearing, made of seven parts copper to one part tin, is more apt to heat than some other alloys. In general, research seems to show that the harder the bearing-metal, the more likely it is to heat.

(3) Good bearing-metal should work well in the foundry. Oxidation while melting causes spongy castings. It can be prevented by a liberal use of powdered charcoal while melting. The addition of 1% to 2% of zinc or a small amount of phosphorus greatly aids in the production of sound castings. This is a principal element of value in phosphor-bronze.

(4) Good bearing-metals should show small friction. It is true that friction is almost wholly a question of the lubricant used; but the metal of the bearing has certainly some influence.

(5) Other things being equal, the best bearing-metal is that which wears slowest.

The principal constituents of bearing-metal alloys are copper, tin, lead, zinc, antimony, iron, and aluminum. The following table gives the constituents of most of the prominent bearing-metals as analyzed at the Pennsylvania Railroad laboratory at Altoona.

| (3) Trace of phosphorus.       | (7) Phosphorus, 0.94.            |
| (4) Possible trace of bismuth. | (8) Phosphorus, 0.20.            |

\* Dr. H. C. Torrey says this analysis is erroneous and that Magnolia metal always contains tin.

As an example of the influence of minute changes in an alloy, the Harrington bronze, which consists of a minute proportion of iron in a copper-zinc alloy, showed after rolling a tensile strength of 75,000 lbs. and 20% elongation in 2 inches.

In experimenting on this subject on the Pennsylvania Railroad, a certain number of the bearings were made of a standard bearing-metal, and the same number were made of the metal to be tested. These bearings were placed on opposite ends of the same axle, one side of the car having the standard bearings, the other the experimental. Before going into service the bearings were carefully weighed, and after a sufficient time they were again weighed.

The standard bearing-metal used is the "S bearing-metal" of the Phosphor-bronze Smelting Co. It contains about 79.70% copper, 9.50% lead, 1% tin, and 0.80% phosphorus. A large number of experiments have shown that the loss of weight of a bearing of this metal is 1 lb. to each 18,000 to 25,000 miles travelled. Besides the measurement of wear, observations were made on the frequency of "hot boxes" with the different metals.

The results of the tests for wear, so far as given, are condensed into the following table;

Metal.	Composition.					Rate of Wear.
	Copper.	Tin.	Lead.	Phos.	Arsenic.	
Standard.....	79.70	10.00	9.50	0.80	.....	100
Copper-tin.....	87.50	12.50	....	....	.....	148
Copper-tin, second experiment, same metal.....						153
Copper-tin, third experiment, same metal.....						147
Arsenic-bronze.....	89.20	10.00	....	....	0.80	142
Arsenic-bronze... ..	79.20	10.00	7.00	....	0.80	115
Arsenic-bronze.....	79.70	10.00	9.50	....	0.80	101
"K" bronze.....	77.00	10.50	12.50	....	....	92
"K" bronze, second experiment, same metal.....						92.7
Alloy "B".....	77.00	8.00	15.00	....	....	86.5

The old copper-tin alloy of 7 to 1 has repeatedly proved its inferiority to the phosphor-bronze metal. Many more of the copper-tin bearings heated than of the phosphor-bronze. The showing of these tests was so satisfactory that phosphor-bronze was adopted as the standard bearing-metal of the Pennsylvania R.R., and was used for a long time.

The experiments, however, were continued. It was found that arsenic practically takes the place of phosphorus in a copper-tin alloy, and three tests were made with arsenic-bronzes as noted above. As the proportion to lead is increased to correspond with the standard, the durability increases as well. In view of these results the "K" bronze was tried, in which neither phosphorus nor arsenic were used, and in which the lead was increased above the proportion in the standard phosphor-bronze. The result was that the metal wore 7.30% slower than the phosphor-bronze. No trouble from heating was experienced with the "K" bronze more than with the standard. Dr. Dudley continues:

At about this time we began to find evidences that wear of bearing-metal alloys varied in accordance with the following law: "That alloy which has the greatest power of distortion without rupture (resilience), will best resist wear." It was now attempted to design an alloy in accordance with this law, taking first the proportions of copper and tin,  $9\frac{1}{2}$  parts copper to 1 of tin was settled on by experiment as the standard, although some evidence since that time tends to show that 12 or possibly 15 parts copper to 1 of tin might have been better. The influence of lead on this copper-tin alloy seems to be much the same as a still further diminution of tin. However, the tendency of the metal to yield under pressure increases as the amount of tin is diminished, and the amount of the lead increased, so a limit is set to the use of lead. A certain amount of tin is also necessary to keep the lead alloyed with the copper.

Bearings were cast of the metal noted in the table as alloy "B," and it wore 13.5% slower than the standard phosphor-bronze. This metal is now the standard bearing-metal of the Pennsylvania Railroad, being slightly changed in composition to allow the use of phosphor-bronze scrap. The formula adopted is: Copper, 105 lbs.; phosphor-bronze, 60 lbs.; tin,  $9\frac{3}{4}$  lbs.; lead,  $25\frac{1}{4}$  lbs. By using ordinary care in the foundry, keeping the metal well covered with charcoal during the melting, no trouble is found in casting good bearings with this metal. The copper and the phosphor-bronze can be put in the pot before putting it in the melting-hole. The tin and lead should be added after the pot is taken from the fire.

It is not known whether the use of a little zinc, or possibly some other combination, might not give still better results. For the present, however, this alloy is considered to fulfil the various conditions required for good bearing-metal better than any other alloy. The phosphor-bronze had an ultimate tensile strength of 30,000 lbs., with 6% elongation, whereas the alloy "B" had 24,000 lbs. tensile strength and 11% elongation.

**White Metal for Engine Bearings.** (Report of a British Naval Committee, *Eng'g*, July 18, 1902.)—For lining bearings, crankpin bushes, and other parts exclusive of cross-head bushes: Tin 12, copper 1, antimony 1. Melt 6 tin 1 copper, and 6 tin 1 antimony separately and mix the two together.

For cross-head bushes a harder alloy, viz., 85% tin, 5% copper, 10% antimony, has given good results.

(For other bearing-metals, see Alloys containing antimony, on next page.)

**ALLOYS CONTAINING ANTIMONY.**

VARIOUS ANALYSES OF BABBITT METAL AND OTHER ALLOYS CONTAINING ANTIMONY.

	Tin.	Copper	Antimony.	Zinc.	Lead.	Bismuth.
Babbitt metal for light duty	50	1	5 parts	.....	.....	.....
Harder Babbitt for bearings*	89.3	1.8	8.9 per ct.	.....	.....	.....

Plate pewter..	89.3	1.8	7.1	.....	.....	1.8
White metal...	85	5	10.	Bearings on Ger. locomotives.		

\* It is mixed as follows: Twelve parts of copper are first melted and then 36 parts of tin are added; 24 parts of antimony are put in, and then 36 parts of tin, the temperature being lowered as soon as the copper is melted in order not to oxidize the tin and antimony, the surface of the bath being protected from contact with the air. The alloy thus made is subsequently remelted in the proportion of 50 parts of alloy to 100 tin. (Joshua Rose.)

**White-metal Alloys.**—The following alloys are used as lining metals by the Eastern Railroad of France (1890):

Number.	Lead.	Antimony.	Tin.	Copper.
1.....	65	25	0	10
2.....	0	11.12	83.33	5.55
3.....	70	20	10	0
4.....	80	8	12	0

No. 1 is used for lining cross-head slides, rod-brasses and axle-bearings; No. 2 for lining axle-bearings and connecting-rod brasses of heavy engines; No. 3 for lining eccentric straps and for bronze slide-valves; and No. 4 for metallic rod-packing.

Some of the best-known white-metal alloys are the following (Circular of Hoveler & Dieckhaus, London, 1893):

	Tin.	Antimony.	Lead.	Copper.	Zinc.
1. Parsons'.....	86	1	2	2	27
2. Richards'.....	70	15	10½	4½	0
3. Babbitt's.....	55	18	23½	3½	0
4. Fentons'.....	16	0	0	5	79
5. French Navy.....	7½	0	7	7	87½
6. German Navy.....	85	7½	0	7½	0

"There are engineers who object to white metal containing lead or zinc. This is, however, a prejudice quite unfounded, inasmuch as lead and zinc often have properties of great use in white alloys."

It is a further fact that an "easy liquid" alloy must not contain more than 18% of antimony, which is an invaluable ingredient of white metal for improving its hardness; but in no case must it exceed that margin, as this would reduce the plasticity of the compound and make it brittle.

Hardest alloy of tin and lead: 6 tin, 4 lead. Hardest of all tin alloys (?): 74 tin, 18 antimony, 8 copper.

Alloy for thin open-work, ornamental castings: Lead 2, antimony 1. White metal for patterns: Lead 10, bismuth 6, antimony 2, common brass 8, tin 10.

**Type-metal** is made of various proportions of lead and antimony, from 17% to 20% antimony according to the hardness desired.

**Babbitt Metals.** (C. R. Tompkins, *Mechanical News*, Jan. 1891.)

The practice of lining journal-boxes with a metal that is sufficiently fusible to be melted in a common ladle is not always so much for the purpose of securing anti-friction properties as for the convenience and cheapness of forming a perfect bearing in line with the shaft without the necessity of

boring them. Boxes that are bored, no matter how accurate, require great care in fitting and attaching them to the frame or other parts of a machine.

It is not good practice, however, to use the shaft for the purpose of casting the bearings, especially if the shaft be steel, for the reason that the hot metal is apt to spring it; the better plan is to use a mandrel of the same size or a trifle larger for this purpose. For slow-running journals, where the load is moderate, almost any metal that may be conveniently melted and will run free will answer the purpose. For wearing properties, with a moderate speed, there is probably nothing superior to pure zinc, but when not combined with some other metal it shrinks so much in cooling that it cannot be held firmly in the recess, and soon works loose; and it lacks those anti-friction properties which are necessary in order to stand high speed.

For line-shafting, and all work where the speed is not over 300 or 400 *r. p. m.*, an alloy of 8 parts zinc and 2 parts block-tin will not only wear longer than any composition of this class, but will successfully resist the force of a heavy load. The tin counteracts the shrinkage, so that the metal, if not overheated, will firmly adhere to the box until it is worn out. But this mixture does not possess sufficient anti-friction properties to warrant its use in fast-running journals.

Among all the soft metals in use there are none that possess greater anti-friction properties than pure lead; but lead alone is impracticable, for it is so soft that it cannot be retained in the recess. But when by any process lead can be sufficiently hardened to be retained in the boxes without materially injuring its anti-friction properties, there is no metal that will wear longer in light fast-running journals. With most of the best and most popular anti-friction metals in use and sold under the name of the Babbitt metal, the basis is lead.

Lead and antimony have the property of combining with each other in all proportions without impairing the anti-friction properties of either. The antimony hardens the lead, and when mixed in the proportion of 80 parts lead by weight with 20 parts antimony, no other known composition of metals possesses greater anti-friction or wearing properties, or will stand a higher speed without heat or abrasion. It runs free in its melted state, has no shrinkage, and is better adapted to light high-speeded machinery than any other known metal. Care, however, should be manifested in using it, and it should never be heated beyond a temperature that will scorch a dry pine stick.

Many different compositions are sold under the name of Babbitt metal. Some are good, but more are worthless; while but very little genuine Babbitt metal is sold that is made strictly according to the original formula. Most of the metals sold under that name are the refuse of type-foundries and other smelting-works, melted and cast into fancy ingots with special brands, and sold under the name of Babbitt metal.

It is difficult at the present time to determine the exact formulas used by the original Babbitt, the inventor of the recessed box, as a number of different formulas are given for that composition. Tin, copper, and antimony were the ingredients, and from the best sources of information the original proportions were as follows :

	Another writer gives:
50 parts tin .....	= 89.3%
2 parts copper .....	= 3.6%
4 parts antimony .....	= 7.1%
	83.3%
	8.3%
	8.3%

The copper was first melted, and the antimony added first and then about ten or fifteen pounds of tin, the whole kept at a dull-red heat and constantly stirred until the metals were thoroughly incorporated, after which the balance of the tin was added, and after being thoroughly stirred again it was then cast into ingots. When the copper is thoroughly melted, and before the antimony is added, a handful of powdered charcoal should be thrown into the crucible to form a flux, in order to exclude the air and prevent the antimony from vaporizing; otherwise much of it will escape in the form of a vapor and consequently be wasted. This metal, when carefully prepared, is probably one of the best metals in use for lining boxes that are subjected to a heavy weight and wear; but for light fast-running journals the copper renders it more susceptible to friction, and it is more liable to heat than the metal composed of lead and antimony in the proportions just given.

**SOLDERS.**

Common solders, equal parts tin and lead; fine solder, 2 tin to 1 lead; cheap solder, 2 lead, 1 tin.

Fusing-point of tin-lead alloys:

Tin 1 to lead 25.....	558° F.
“ 1 “ “ 10.....	541
“ 1 “ “ 5.....	511
“ 1 “ “ 3.....	482
“ 1 “ “ 2.....	441
“ 1 “ “ 1.....	370

Tin 1½ to lead 1... ..	334° F.
“ 2 “ “ 1.....	340
“ 3 “ “ 1... ..	356
“ 4 “ “ 1.....	365
“ 5 “ “ 1.....	378
“ 6 “ “ 1.....	381

Common pewter contains 4 lead to 1 tin.

Gold solder: 14 parts gold, 6 silver, 4 copper. Gold solder for 14-carat gold: 25 parts gold, 25 silver, 12½ brass, 1 zinc.

Silver solder: Yellow brass 70 parts, zinc 7, tin 11½. Another: Silver 145 parts, brass (3 copper, 1 zinc) 73, zinc 4.

German-silver solder: Copper 38, zinc 54, nickel 8.

Novel's solders for aluminum:

Tin 100 parts, lead 5;	melts at 536° to 572° F.
“ 100 “ zinc 5;	“ 536 to 612
“ 1000 “ copper 10 to 15;	“ 662 to 842
“ 1000 “ nickel 10 to 15;	“ 662 to 842

Novel's solder for aluminum bronze: Tin 900 parts, copper 100, bismuth 2 to 3. It is claimed that this solder is also suitable for joining aluminum to copper, brass, zinc, iron, or nickel.

**Working Load, Diameter, and Weight of Ropes and Chains.** (Klein's Weisbach, vol. iii, part 1, sec. 2, p. 561.)

Hemp ropes:  $d$  = diam. of rope. Wire rope:  $d$  = diam. of wire,  $n$  = number of wires,  $G$  = weight per running foot,  $k$  = permissible load in pounds per square inch of section,  $P$  = permissible load on rope or chain. Oval chains:  $d$  = diam. of iron used; inside dimensions of oval  $1.5d$  and  $2.6d$ . Each link is a piece of chain  $2.6d$  long.  $G_0$  = weight of a single link =  $2.10d^3$  lbs.;  $G$  = weight per running foot =  $9.73d^2$  lbs.

	Hemp Rope.		Wire Rope.
	Dry and Untarred.	Wet or Tarred.	
$k$ (lbs.) =	1420	1160	17000
$d$ (ins.) =	$0.03 \sqrt{P}$	$0.033 \sqrt{P}$	$0.0087 \sqrt{\frac{P}{n}}$
$P$ (lbs.) =	$1120d^2 = 2855G$	$916d^2 = 1975G$	$13350nd^2 = 4590G$
$G$ (lbs.) =	$1.28d^2 = 0.00035P$	$1.54d^2 = 0.0005P$	$2.91nd^2 = 0.000218P$
	Open-link Chain.		Stud-link Chain.
$k$ (lbs.) =	8500		11400
$d$ (ins.) =	$0.0087 \sqrt{P}$		$0.0076 \sqrt{P}$
$P$ (lbs.) =	$13350d^2 = 1360G$		$17800d^2 = 1660G$
$G$ (lbs.) =	$9.73d^2 = 0.000737P$		$10.65d^2 = 0.0006P$

Stud Chains 4/3 times as strong as open-link variety. [This is contrary to the statements of Capt. Beardslee, U. S. N., in the report of the U. S. Test Board. He holds that the open link is stronger than the studded link. See p. 308 ante].

STRENGTH AND WEIGHT OF WIRE ROPE, HEMPEN ROPE, AND CHAIN CABLES. (Klein's Weisbach.)

Sometimes, when the depths are very great, ropes are given approximately the form of a body of uniform strength, by making them of separate pieces, whose diameters diminish towards the lower end. It is evident that by this means the tensions in the fibres caused by the rope's own weight can be considerably diminished.

**Rope for Hoisting or Transmission. Manila Rope.** (C. W. Hunt Company, New York.)—Rope used for hoisting or for transmission of power is subjected to a very severe test. Ordinary rope chafes and grinds to powder in the centre, while the exterior may look as though it was little worn.

In bending a rope over a sheave, the strands and the yarns of these strands slide a small distance upon each other, causing friction, and wear the rope internally.

The "Stevedore" rope used by the C. W. Hunt Co. is made by lubricating the fibres with plumbago, mixed with sufficient tallow to hold it in position. This lubricates the yarns of the rope, and prevents internal chafing and wear. After running a short time the exterior of the rope gets compressed and coated with the lubricant.

In manufacturing rope, the fibres are first spun into a yarn, this yarn being twisted in a direction called "right hand." From 20 to 80 of these yarns, depending on the size of the rope, are then put together and twisted in the opposite direction, or "left hand," into a strand. Three of these

strands, for a 3-strand, or four for a 4-strand rope, are then twisted together, the twist being again in the "right hand" direction. When the strand is twisted, it untwists each of the threads, and when the three strands are twisted together into rope, it untwists the strands, but again twists up the threads. It is this opposite twist that keeps the rope in its proper form. When a weight is hung on the end of a rope, the tendency is for the rope to untwist, and become longer. In untwisting the rope, it would twist the threads up, and the weight will revolve until the strain of the untwisting strands just equals the strain of the threads being twisted tighter. In making a rope it is impossible to make these strains exactly balance each other. It is this fact that makes it necessary to take out the "turns" in a new rope, that is, untwist it when it is put at work. The proper twist that should be put in the threads has been ascertained approximately by experience.

The amount of work that the rope will do varies greatly. It depends not only on the quality of the fibre and the method of laying up the rope, but also on the kind of weather when the rope is used, the blocks or sheaves over which it is run, and the strain in proportion to the strain put upon the rope. The principal wear comes in practice from defective or badly set sheaves, from excess of load and exposure to storms.

The loads put upon the rope should not exceed those given in the tables, for the most economical wear. The indications of excessive load will be the twist coming out of the rope, or one of the strands slipping out of its proper position. A certain amount of twist comes out in using it the first day or two, but after that the rope should remain substantially the same. If it does not, the load is too great for the durability of the rope. If the rope wears on the outside, and is good on the inside, it shows that it has been chafed in running over the pulleys or sheaves. If the blocks are very small, it will increase the sliding of the strands and threads, and result in a more rapid internal wear. Rope made for hoisting and for rope transmission is usually made with four strands, as experience has shown this to be the most serviceable.

The strength and weight of "stevedore" rope is estimated as follows:

Breaking strength in pounds =  $720$  (circumference in inches)<sup>2</sup>;  
Weight in pounds per foot =  $.032$  (circumference in inches)<sup>2</sup>.

**The Technical Words relating to Cordage** most frequently heard are:

**YARN.**—Fibres twisted together.

**THREAD.**—Two or more *small yarns* twisted together.

**STRING.**—The same as a thread but a little larger *yarns*.

**STRAND.**—Two or more *large yarns* twisted together.

**CORD.**—Several threads twisted together.

**ROPE.**—Several *strands* twisted together.

**HAWSER.**—A rope of three *strands*.

**SHROUD-LAID.**—A rope of four *strands*.

**CABLE.**—Three hawsers twisted together.

**YARNS** are laid up left-handed into *strands*.

**STRANDS** are laid up right-handed into rope.

**HAWSERS** are laid up left-handed into a cable.

A rope is:

**LAI**D by twisting strands together in making the rope.

**SPLICED** by joining to another rope by interweaving the strands.

**WHIPPED.**—By winding a string around the end to prevent untwisting.

**SERVED.**—When covered by winding a yarn continuously and tightly around it.

**PARCELED.**—By wrapping with canvas.

**SEIZED.**—When two parts are bound together by a yarn, thread or string.

**PAYED.**—When painted, tarred or greased to resist wet.

**HAUL.**—To pull on a rope.

**TAUT.**—Drawn tight or strained.

**Splicing of Ropes.**—The splice in a transmission rope is not only the weakest part of the rope but is the first part to fail when the rope is worn out. If the rope is larger at the splice, the projecting part will wear on the pulleys and the rope fail from the cutting off of the strands. The following directions are given for splicing a 4-strand rope.

The engravings show each successive operation in splicing a  $1\frac{3}{4}$  inch manila rope. Each engraving was made from a full-size specimen.

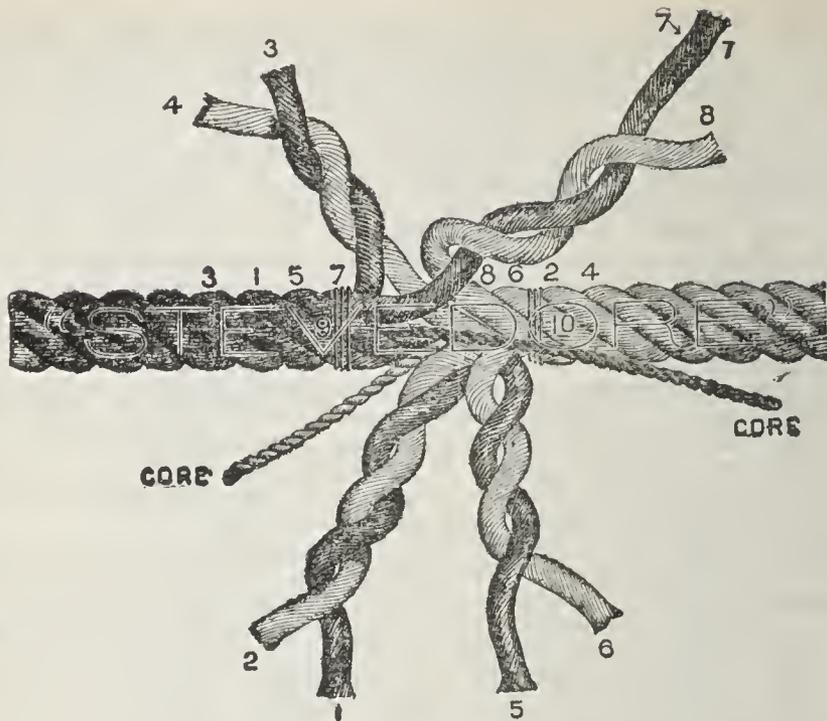

FIG. 78.

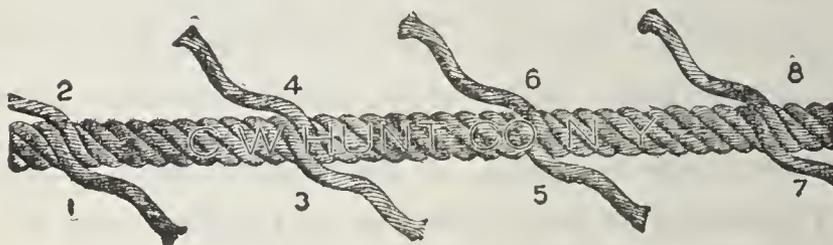

FIG. 79.

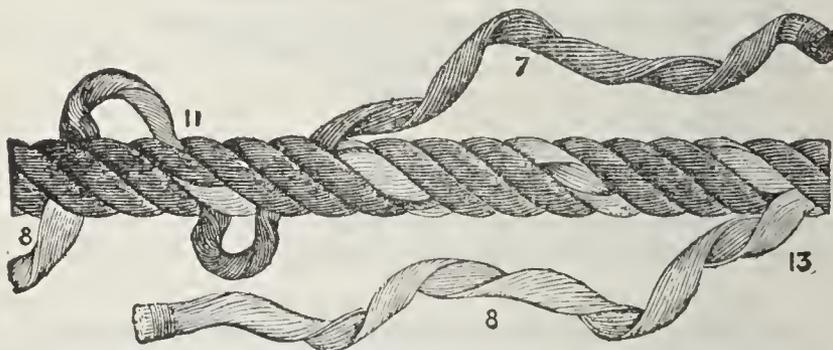

FIG. 80.

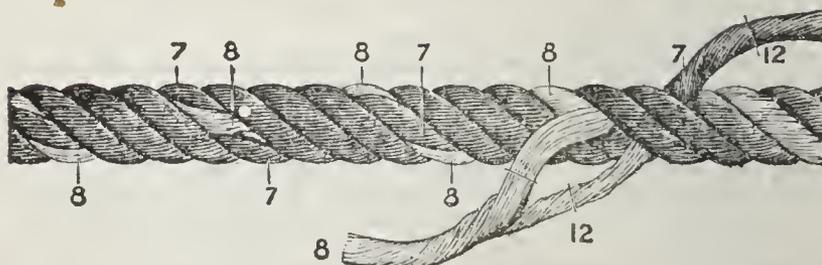

FIG. 81.

SPLICING OF ROPES.

Tie a piece of twine, 9 and 10, around the rope to be spliced, about 6 feet from each end. Then unlay the strands of each end back to the twine.

Butt the ropes together and twist each corresponding pair of strands loosely, to keep them from being tangled, as shown in Fig. 78.

The twine 10 is now cut, and the strand 8 unlaied and strand 7 carefully laid in its place for a distance of four and a half feet from the junction.

The strand 6 is next unlaied about one and a half feet and strand 5 laid in its place.

The ends of the cores are now cut off so they just meet.

Unlay strand 1 four and a half feet, laying strand 2 in its place.

Unlay strand 3 one and a half feet, laying in strand 4.

Cut all the strands off to a length of about twenty inches, for convenience in manipulation.

The rope now assumes the form shown in Fig. 79 with the meeting points of the strands three feet apart.

Each pair of strands is successively subjected to the following operation:

From the point of meeting of the strands 8 and 7, unlay each one three turns; split both the strand 8 and the strand 7 in halves as far back as they are now unlaied and "whip" the end of each half strand with a small piece of twine.

The half of the strand 7 is now laid in three turns and the half of 8 also laid in three turns. The half strands now meet and are tied in a simple knot, 11, Fig. 80, making the rope at this point its original size.

The rope is now opened with a marlin spike and the half strand of 7 worked around the half strand of 8 by passing the end of the half strand 7 through the rope, as shown in the engraving, drawn taut and again worked around this half strand until it reaches the half strand 13 that was not laid in. This half strand 13 is now split, and the half strand 7 drawn through the opening thus made, and then tucked under the two adjacent strands, as shown in Fig. 81. The other half of the strand 8 is now wound around the other half strand 7 in the same manner. After each pair of strands has been treated in this manner, the ends are cut off at 12, leaving them about four inches long. After a few days' wear they will draw into the body of the rope or wear off, so that the locality of the splice can scarcely be detected.

**Coal Hoisting.** (C. W. Hunt Co.).—The amount of coal that can be hoisted with a rope varies greatly. Under the ordinary conditions of use a rope hoists from 5000 to 8000 tons. Where the circumstances are more favorable, the amounts run up frequently to 12,000 or 15,000 tons, occasionally to 20,000 and in one case 32,400 tons to a single fall.

When a hoisting rope is first put in use, it is likely from the strain put upon it to twist up when the block is loosened from the tub. This occurs in the first day or two only. The rope should then be taken down and the "turns" taken out of the rope. When put up again the rope should give no further trouble until worn out.

It is necessary that the rope should be much larger than is needed to bear the strain from the load.

Practical experience for many years has substantially settled the most economical size of rope to be used which is given in the table below.

Hoisting ropes are not spliced, as it is difficult to make a splice that will not pull out while running over the sheaves, and the increased wear to be obtained in this way is very small.

Coal is usually hoisted with what is commonly called a "double whip;" that is, with a running block that is attached to the tub which reduces the strain on the rope to approximately one half the weight of the load hoisted. The following table gives the usual sizes of hoisting rope and the proper working strain:

**Stevedore Hoisting-rope.**

C. W. Hunt Co.

Circumference of the rope in ins.	Proper Working Strain on the Rope in lbs.	Nominal size of Coal tubs. Double whip.	Approximate Weight of a Coil, in lbs.
3	350	1/6 to 1/5 tons.	360
3 1/2	500	1/5 " 1/4 "	480
4	650	1/4 " 1/3 "	650
4 1/2	800	1/2 " 3/4 "	830
5	1000	3/4 " 1 "	960

Hoisting rope is ordered by circumference, transmission rope by diameter.

### Weight and Strength of Manila Rope.

Spencer Miller (*Eng'g News*, Dec. 6, 1890) gives a table of breaking strength of manila rope, which he considers more reliable than the strength computed by Mr. Hunt's formula: Breaking strength =  $720 \times (\text{circumference in inches})^2$ . Mr. Miller's formula is: Breaking weight lbs. = circumference<sup>2</sup> × a coefficient which varies from 900 for  $\frac{1}{2}$ " to 700 for 2" diameter rope, as below:

Circumference ...	$1\frac{1}{2}$	2	$2\frac{1}{2}$	$2\frac{3}{4}$	3	$3\frac{1}{2}$	$3\frac{3}{4}$	$4\frac{1}{4}$	$4\frac{1}{2}$	5	$5\frac{1}{2}$	6
Coefficient .....	900	845	820	790	780	765	760	745	735	725	712	700

The following table gives the breaking strength of manila rope as calculated by Mr. Hunt's formula, and also by Mr. Miller's, using in the latter the coefficient 900 for sizes below  $1\frac{1}{2}$  in. circumference and 700 for sizes above 6 in. The differences between the figures for any given size are probably not greater than the difference in actual strength of samples from different makers. Both sets of figures are considerably lower than those given in tables published by some makers of rope, but they are believed to be more reliable. The figures for weight per 100 ft. are from manufacturers' tables.

Diameter in inches.	Circumference in inches.	Weight of 100 Feet of Rope in lbs.	Ultimate Strength of Rope in lbs.		Diameter in inches.	Circumference in inches.	Weight of 100 Feet of Rope in lbs.	Ultimate Strength of Rope in lbs.	
			Hunt.	Miller.				Hunt.	Miller.
$\frac{3}{16}$	$\frac{9}{16}$	2	230	280	$1\frac{5}{16}$	4	52	11,500	12,000
$\frac{1}{4}$	$\frac{3}{4}$	3	400	500	$1\frac{3}{8}$	$4\frac{1}{4}$	58	13,000	13,500
$\frac{5}{16}$	1	4	630	790	$1\frac{1}{2}$	$4\frac{1}{2}$	65	14,600	14,900
$\frac{3}{8}$	$1\frac{1}{8}$	5	900	1,140	$1\frac{9}{16}$	$4\frac{3}{4}$	$72\frac{1}{2}$	16,200	16,500

$\frac{9}{16}$	$1\frac{3}{4}$	11	2,050	2,480	2	6	113	25,900	25,200
$\frac{5}{8}$	2	$13\frac{1}{3}$	2,880	3,380	$2\frac{1}{8}$	$6\frac{1}{2}$	133	30,400	29,600
$\frac{3}{4}$	$2\frac{1}{4}$	$16\frac{1}{3}$	3,610	4,150	$2\frac{1}{4}$	7	153	35,300	34,300
$1\frac{1}{16}$	$2\frac{1}{2}$	20	4,500	5,030	$2\frac{1}{2}$	$7\frac{1}{4}$	184	40,500	39,400
$\frac{7}{8}$	$2\frac{3}{4}$	$23\frac{2}{3}$	5,440	5,970	$2\frac{5}{8}$	8	211	46,100	44,800
1	3	$28\frac{1}{3}$	6,480	7,020	$2\frac{7}{8}$	$8\frac{1}{2}$	237	52,000	50,600
$1\frac{1}{16}$	$3\frac{1}{4}$	$33\frac{1}{3}$	7,600	8,160	3	9	262	58,300	56,700
$1\frac{1}{8}$	$3\frac{1}{2}$	38	8,820	9,370	$3\frac{1}{8}$	$9\frac{1}{2}$	293	65,000	63,200
$1\frac{1}{4}$	$3\frac{3}{4}$	45	10,120	10,690	$3\frac{1}{4}$	10	325	72,000	70,000

For rope-driving Mr. Hunt recommends that the working strain should not exceed  $\frac{1}{20}$  of the ultimate breaking strain. For further data on ropes see "Rope-driving."

**Knots.**—A great number of knots have been devised of which a few only are illustrated, but those selected are the most frequently used. In the cuts, Fig. 82, they are shown open, or before being drawn taut, in order to show the position of the parts. The names usually given to them are:

- |                                 |                                 |
|---------------------------------|---------------------------------|
| A. Bight of a rope.             | P. Flemish loop.                |
| B. Simple or Overhand knot.     | Q. Chain knot with toggle.      |
| C. Figure 8 knot.               | R. Half-hitch.                  |
| D. Double knot.                 | S. Timber-hitch.                |
| E. Boat knot.                   | T. Clove-hitch.                 |
| F. Bowline, first step.         | U. Rolling-hitch.               |
| G. Bowline, second step.        | V. Timber-hitch and half-hitch. |
| H. Bowline completed.           | W. Blackwall-hitch.             |
| I. Square or reef knot.         | X. Fisherman's bend.            |
| J. Sheet bend or weaver's knot. | Y. Round turn and half-hitch.   |
| K. Sheet bend with a toggle.    | Z. Wall knot commenced.         |
| L. Carrick bend.                | A A. " " completed.             |
| M. Stevedore knot completed.    | B B. Wall knot crown commenced. |
| N. Stevedore knot commenced.    | C C. " " " completed.           |
| O. Slip knot.                   |                                 |

The principle of a knot is that no two parts, which would move in the same direction if the rope were to slip, should lay along side of and touching each other.

The bowline is one of the most useful knots, it will not slip, and after being strained is easily untied. Commence by making a bight in the rope, then put the end through the bight and under the standing part as shown in *G*, then pass the end again through the bight, and haul tight.

The square or reef knot must not be mistaken for the "granny" knot that slips under a strain. Knots *H*, *K* and *M* are easily untied after being under strain. The knot *M* is useful when the rope passes through an eye and is held by the knot, as it will not slip and is easily untied after being strained.

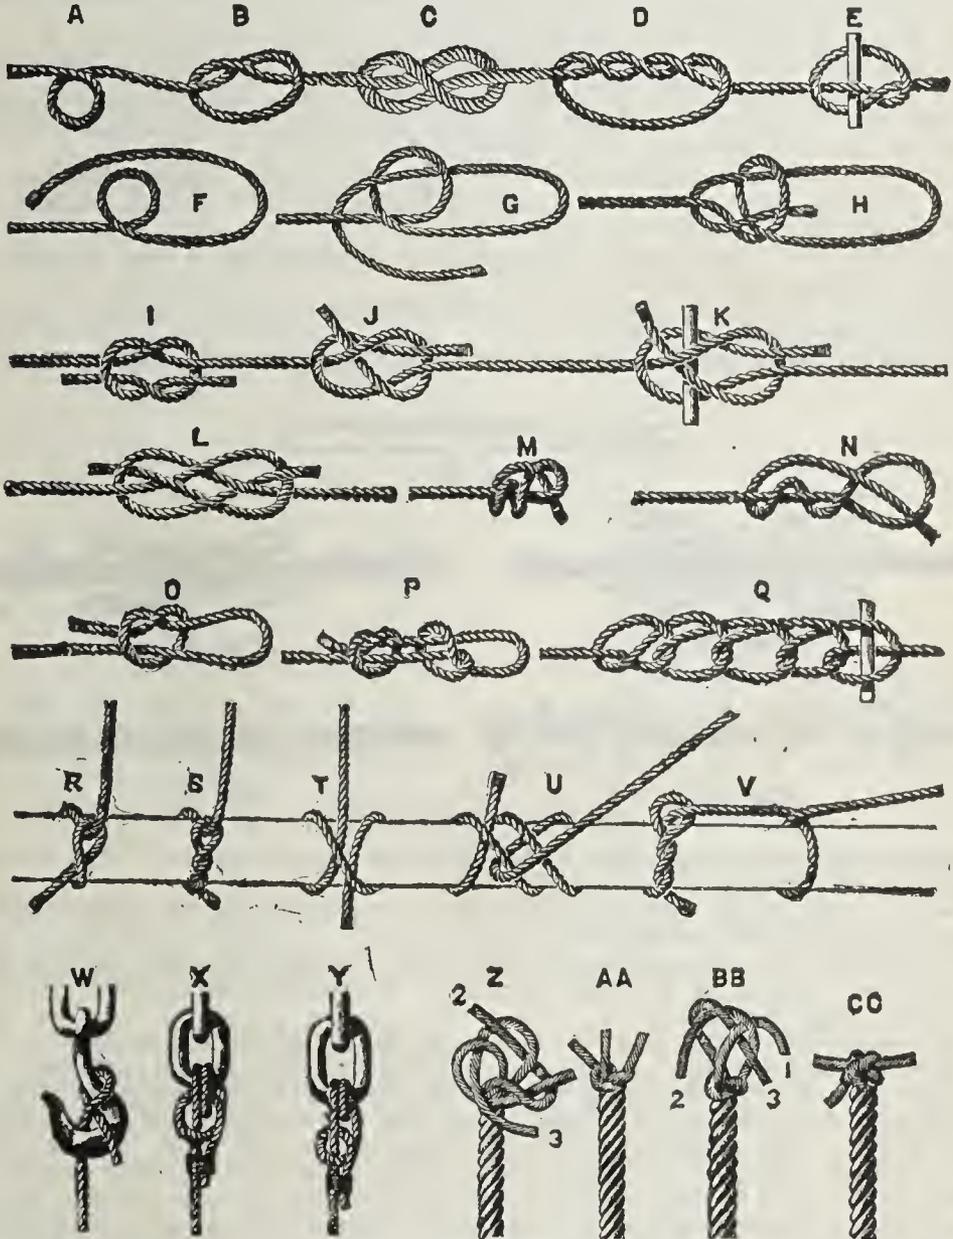

FIG. 82.—KNOTS.

The timber hitch *S* looks as though it would give way, but it will not; the greater the strain the tighter it will hold. The wall knot looks complicated, but is easily made by proceeding as follows: Form a bight with strand 1 and pass the strand 2 around the end of it, and the strand 3 round the end of 2 and then through the bight of 1 as shown in the cut *Z*. Haul the ends taut when the appearance is as shown in *AA*. The end of the strand 1 is now laid over the centre of the knot, strand 2 laid over 1 and 3 over 2, when the end of 3 is passed through the bight of 1 as shown in *BB*. Haul all the strands taut as shown in *CC*.

**To Splice a Wire Rope.**—The tools required will be a small marline spike, nipping cutters, and either clamps or a small hemp-rope sling with which to wrap around and untwist the rope. If a bench-vise is accessible it will be found convenient.

In splicing rope, a certain length is used up in making the splice. An allowance of not less than 16 feet for  $\frac{1}{2}$  inch rope, and proportionately longer for larger sizes, must be added to the length of an endless rope in ordering.

Having measured, carefully, the length the rope should be after splicing, and marked the points  $M$  and  $M'$ , Fig. 83, unlay the strands from each end  $E$  and  $E'$  to  $M$  and  $M'$  and cut off the centre at  $M$  and  $M'$ , and then:

(1). Interlock the six unlay strands of each end alternately and draw them together so that the points  $M$  and  $M'$  meet, as in Fig. 84.

(2). Unlay a strand from one end, and following the unlay closely, lay into the seam or groove it opens, the strand opposite it belonging to the other end of the rope, until within a length equal to three or four times the length of one lay of the rope, and cut the other strand to about the same length from the point of meeting as at  $A$ , Fig. 85.

(3). Unlay the adjacent strand in the opposite direction, and following the unlay closely, lay in its place the corresponding opposite strand, cutting the ends as described before at  $B$ , Fig. 85.

There are now four strands laid in place terminating at  $A$  and  $B$ , with the eight remaining at  $M M'$ , as in Fig. 85.

It will be well after laying each pair of strands to tie them temporarily at the points  $A$  and  $B$ .

Pursue the same course with the remaining four pairs of opposite strands,

FIG. 83.

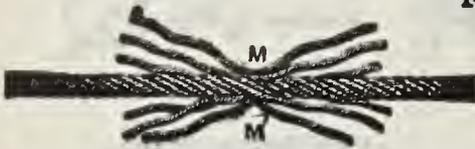

FIG. 84.

FIG. 85.

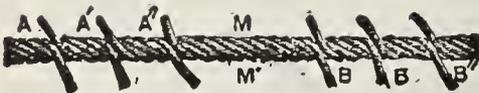

FIG. 86.

FIG. 87.

#### SPLICING WIRE ROPE.

stopping each pair about eight or ten turns of the rope short of the preceding pair, and cutting the ends as before.

We now have all the strands laid in their proper places with their respective ends passing each other, as in Fig. 86.

All methods of rope-splicing are identical to this point; their variety consists in the method of tucking the ends. The one given below is the one most generally practiced.

Clamp the rope either in a vise at a point to the left of  $A$ , Fig. 86, and by a hand-clamp applied near  $A$ , open up the rope by untwisting sufficiently to cut the core at  $A$ , and seizing it with the nippers, let an assistant draw it out slowly, you following it closely, crowding the strand in its place until it is all laid in. Cut the core where the strand ends, and push the end back into its place. Remove the clamps and let the rope close together around it. Draw out the core in the opposite direction and lay the other strand in the centre of the rope, in the same manner. Repeat the operation at the five remaining points, and hammer the rope lightly at the points where the ends pass each other at  $A, A, B, B,$  etc., with small wooden mallets, and the splice is complete, as shown in Fig. 87.

If a clamp and vise are not obtainable, two rope slings and short wooden levers may be used to untwist and open up the rope.

A rope spliced as above will be nearly as strong as the original rope and smooth everywhere. After running a few days, the splice, if well made, cannot be found except by close examination.

The above instructions have been adopted by the leading rope manufacturers of America.

SPRINGS.

**Definitions.**—A spiral spring is one which is wound around a fixed point or centre, and continually receding from it like a watch spring. A helical spring is one which is wound around an arbor, and at the same time advancing like the thread of a screw. An elliptical or laminated spring is made of flat bars, plates, or “leaves,” of regularly varying lengths, superposed one upon the other.

**Laminated Steel Springs.**—Clark (Rules, Tables and Data) gives the following from his work on *Railway Machinery*, 1855:

$$\Delta = \frac{1.66L^3}{bt^3n}; \quad s = \frac{bt^2n}{11.3L}; \quad n = \frac{1.66L^3}{\Delta bt^3};$$

- $\Delta$  = elasticity, or deflection, in sixteenths of an inch per ton of load,
- $s$  = working strength, or load, in tons (2240 lbs.),
- $L$  = span, when loaded, in inches,
- $b$  = breadth of plates, in inches, taken as uniform,
- $t$  = thickness of plates, in sixteenths of an inch,
- $n$  = number of plates.

NOTE.—The span and the elasticity are those due to the spring when weighted.

2. When extra thick back and short plates are used, they must be replaced by an equivalent number of plates of the ruling thickness, prior to the employment of the first two formulæ. This is found by multiplying the number of extra thick plates by the cube of their thickness, and dividing by the cube of the ruling thickness. Conversely, the number of plates of the ruling thickness given by the third formula, required to be deducted and replaced by a given number of extra thick plates, are found by the same calculation.

3. It is assumed that the plates are similarly and regularly formed, and that they are of uniform breadth, and but slightly taper at the ends.

Reuleaux’s Constructor gives for semi-elliptic springs:

$$P = \frac{Snbh^2}{6l} \quad \text{and} \quad f = \frac{6Pl^3}{Enbh^3};$$

- $S$  = max. direct fibre-strain in plate;
- $n$  = number of plates in spring;
- $l$  = one half length of spring;
- $P$  = load on one end of spring;
- $b$  = width of plates;
- $h$  = thickness of plates;
- $f$  = deflection of end of spring;
- $E$  = modulus of direct elasticity.

The above formula for deflection can be relied upon where all the plates of the spring are regularly shortened; but in semi-elliptic springs, as used, there are generally several plates extending the full length of the spring, and the proportion of these long plates to the whole number is usually about one fourth. In such cases  $f = \frac{5.5Pl^3}{Enbh^3}$ . (G. R. Henderson, Trans. A. S. M. E., vol. xvi.)

In order to compare the formulæ of Reuleaux and Clark we may make the following substitutions in the latter:  $s$  in tons =  $P$  in lbs.  $\div$  1120;  $\Delta s = 16f$ ;  $L = 2l$ ;  $t = 16h$ ; then

$$\Delta s = 16f = \frac{1.66 \times 8l^3 \times P}{4096 \times 1120 \times nbh^3}, \quad \text{whence} \quad f = \frac{Pl^3}{5,527,133},$$

which corresponds with Reuleaux’s formula for deflection if in the latter we take  $E = 33,162,800$ .

$$\text{Also} \quad s = \frac{P}{1120} = \frac{256nbh^2}{11.3 \times 2l}, \quad \text{whence} \quad P = \frac{12,687nbh^2}{l},$$

which corresponds with Reuleaux’s formula for working load when  $S$  in the latter is taken at 76,120.

The value of  $E$  is usually taken at 30,000,000 and  $S$  at 80,000, in which case Reuleaux’s formulæ become

$$P = \frac{13,333nbh^2}{l} \quad \text{and} \quad f = \frac{Pl^3}{5,000,000nbh^3}.$$

**Helical Steel Springs.**—Clark quotes the following from the report on Safety Valves (Trans. Inst. Engrs. and Shipbuilders in Scotland, 1874-5):

$$E = \frac{d^3 \times w}{D^4 \times C}.$$

$E$  = compression or extension of one coil in inches,  
 $d$  = diameter from centre to centre of steel bar constituting the spring,  
 in inches,  
 $w$  = weight applied, in pounds,  
 $D$  = diameter, or side of the square, of the steel bar, in sixteenths of an  
 inch,  
 $C$  = a constant, which may be taken as 22 for round steel and 30 for  
 square steel.

NOTE.—The deflection  $E$  for one coil is to be multiplied by the number of  
 free coils, to obtain the total deflection for a given spring.

The relation between the safe load, size of steel, and diameter of coil, may  
 be taken for practical purposes as follows:

$$D = \sqrt[3]{\frac{wd}{3}}, \text{ for round steel;}$$

$$D = \sqrt[3]{\frac{wd}{4.29}}, \text{ for square steel.}$$

Rankine's Machinery and Millwork, p. 390, gives the following:

$$\frac{W}{v} = \frac{cd^4}{64nr^3}; \quad W_1 = \frac{.196fd^3}{r}; \quad v_1 = \frac{12.566nfr^2}{cd};$$

$$\frac{W_1}{2} = \text{greatest safe sudden load.}$$

In which  $d$  is the diameter of wire in inches;  $c$  a co-efficient of transverse  
 elasticity of wire, say 10,500,000 to 12,000,000 for charcoal iron wire and steel;  
 $r$  radius to centre of wire in coil;  $n$  effective number of coils;  $f$  greatest safe  
 shearing stress, say 30,000;  $W$  any load not exceeding greatest safe load;  
 $v$  corresponding extension or compression;  $W_1$  greatest safe load; and  $v_1$   
 greatest safe steady extension or compression.

If the wire is square, of the dimensions  $d \times d$ , the load for a given deflec-  
 tion is greater than for a round wire of the diameter  $d$  in the ratio of 2.81 to  
 1.96 or of 1.43 to 1, or of 10 to 7, nearly.

Wilson Hartnell (Proc. Inst. M. E., 1882, p. 426), says: The size of a spiral  
 spring may be calculated from the formula on page 304 of "Rankine's Use-  
 ful Rules and Tables"; but the experience with Salter's springs has shown  
 that the safe limit of stress is more than twice as great as there given,  
 namely 60,000 to 70,000 lbs. per square inch of section with  $\frac{3}{8}$  inch wire, and  
 about 50,000 with  $\frac{1}{2}$  inch wire. Hence the work that can be done by  
 springs of wire is four or five times as great as Rankine allows.

For  $\frac{3}{8}$  inch wire and under,

$$\text{Maximum load in lbs.} = \frac{12,000 \times (\text{diam. of wire})^3}{\text{Mean radius of springs}};$$

$$\text{Weight in lbs. to deflect spring 1 in.} = \frac{180,000 \times (\text{diam.})^4}{\text{Number of coils} \times (\text{rad.})^3}.$$

The work in foot-pounds that can be stored up in a spiral spring would  
 lift it above 50 ft.

In a few rough experiments made with Salter's springs the coefficient of  
 rigidity was noticed to be 12,600,000 to 13,700,000 with  $\frac{1}{4}$  inch wire; 11,000,000  
 for  $11/32$  inch; and 10,600,000 to 10,900,000 for  $\frac{3}{8}$  inch wire.

**Helical Springs.**—J. Begtrup, in the *American Machinist* of Aug.  
 18, 1892, gives formulas for the deflection and carrying capacity of helical  
 springs of round and square steel, as follow:

$$\left. \begin{aligned} W &= .3927 \frac{Sd^3}{D-d}, \\ F &= 8 \frac{P(D-d)^3}{Ed^4}, \end{aligned} \right\} \text{ for round steel.}$$

$$\left. \begin{aligned} W &= .471 \frac{Sd^3}{D-d}, \\ F &= 4.712 \frac{P(D-d)^3}{Ed^4}, \end{aligned} \right\} \text{ for square steel.}$$

- $W$  = carrying capacity in pounds,
- $S$  = greatest tensile stress per square inch of material,
- $d$  = diameter of steel,
- $D$  = outside diameter of coil,
- $F$  = deflection of one coil,
- $E$  = torsional modulus of elasticity,
- $P$  = load in pounds.

From these formulas the following table has been calculated by Mr. Begtrup. A spring being made of an elastic material, and of such shape as to allow a great amount of deflection, will not be affected by sudden shocks or blows to the same extent as a rigid body, and a factor of safety very much less than for rigid constructions may be used.

HOW TO USE THE TABLE.

When designing a spring for continuous work, as a car spring, use a greater factor of safety than in the table; for intermittent working, as in a steam-engine governor or safety valve, use figures given in table; for square steel multiply line  $W$  by 1.2 and line  $F$  by .59.

*Example 1.*—How much will a spring of  $\frac{3}{8}$ " round steel and 3" outside diameter carry with safety? In the line headed  $D$  we find 3, and right underneath 473, which is the weight it will carry with safety. How many coils must this spring have so as to deflect 3" with a load of 400 pounds? Assuming a modulus of elasticity of 12 millions we find in the centre line headed  $F$  the figure .0610; this is deflection of one coil for a load of 100 pounds; therefore  $.061 \times 4 = .244$ " is deflection of one coil for 400 pounds load, and  $3 \div .244 = 12\frac{1}{2}$  is the number of coils wanted. This spring will therefore be  $43\frac{1}{4}$ " long when closed, counting working coils only, and stretch to  $73\frac{1}{4}$ ".

*Example 2.*—A spring  $3\frac{1}{4}$ " outside diameter of  $\frac{7}{16}$ " steel is wound close; how much can it be extended without exceeding the limit of safety? We find maximum safe load for this spring to be 702 pounds, and deflection of one coil for 100 pounds load .0405 inches; therefore  $7.02 \times .0405 = .284$ " is the greatest admissible opening between coils. We may thus, without knowing the load, ascertain whether a spring is overloaded or not.

**Carrying Capacity and Deflection of Helical Springs of Round Steel.**

$d$  = diameter of steel.  $D$  = outside diameter of coil.  $W$  = safe working load in pounds—tensile stress not exceeding 60,000 pounds per square inch.  $F$  = deflection by a load of 100 pounds of one coil, and a modulus of elasticity of 10, 12 and 14 millions respectively. The ultimate carrying capacity will be about twice the safe load.

The formulæ for deflection or compression given by Clark, Hartnell, and Begtrup, although very different in form, show a substantial agreement when reduced to the same form. Let  $d$  = diameter of wire in inches,  $D_1$  = mean diameter of coil,  $n$  the number of coils,  $w$  the applied weight in pounds, and  $C$  a coefficient, then

Compression or extension of one coil =  $\frac{wD_1^3}{Cd^4}$ ;

Weight in pounds to cause comp. or ext. of 1 in. =  $\frac{Cd^4}{nD_1^3}$ .

The coefficient  $C$  reduced from Hartuell's formula is  $8 \times 180,000 = 1,440,000$ ; according to Clark,  $16^4 \times 22 = 1,441,792$ , and according to Begtrup (using 12,000,000 for the torsional modulus of elasticity) =  $12,000,000 \div 8 = 1,500,000$ .

Rankine's formula for greatest safe extension,  $v_1 = \frac{12,566nfr^2}{cd}$  may take

the form  $v_1 = \frac{.7854nD_1^2}{100d}$  if we use 30,000 and 12,000,000 as the values for  $f$  and  $c$  respectively.

The several formulæ for safe load given above may be thus compared, letting  $d$  = diameter of wire, and  $D_1$  = mean diameter of coil, Rankine,

$W = \frac{.196fd^3}{r}$ ; Clark,  $W = \frac{3(d \times 16)^3}{D_1}$ ; Begtrup,  $W = \frac{.3927Sd^3}{D_1}$ ; Hartnell,

$W = \frac{12000at^3}{r}$ . Substituting for  $f$  the value 30,000 given by Rankine, and for

$S$ , 60,000 as given by Begtrup, we have  $W = 11,760 \frac{d^3}{D_1}$  Rankine;  $12,288 \frac{d^3}{D_1}$

Clark;  $23,562 \frac{d^3}{D_1}$  Begtrup;  $24,000 \frac{d^3}{D_1}$  Hartnell.

Taking from the Pennsylvania Railroad specifications the capacity when closed of the following springs, in which  $d$  = diameter of wire,  $D$  diameter outside of coil,  $D_1 = D - d$ ,  $c$  capacity,  $H$  height when free, and  $h$  height when closed, all in inches.

No.	$T$ .	$d = \frac{1}{4}$	$D = 1\frac{1}{2}$	$D_1 = 1\frac{1}{4}$	$c = 400$	$H = 9$	$h = 6$
S.		$\frac{1}{2}$	3	$2\frac{1}{2}$	1,900	8	5
K.		$\frac{3}{4}$	$5\frac{3}{4}$	5	2,100	7	$4\frac{1}{4}$
D.		1	5	4	8,100	$10\frac{1}{2}$	8

C.		$1\frac{1}{8}$	$4\frac{7}{8}$	$3\frac{3}{4}$	16,000	$4\frac{3}{8}$	$3\frac{3}{8}$

and substituting the values of  $c$  in the formula  $c = W = x \frac{d^3}{D_1}$  we find  $x$ , the

coefficient of  $\frac{d^3}{D_1}$  to be respectively 32,000; 38,000; 32,400; 24,888; 34,560; 42,140, average 34,000.

Taking 12,900 as the coefficient of  $\frac{d^3}{D_1}$  according to Rankine and Clark for safe load, and 24,000 as the coefficient according to Begtrup and Hartnell, we have for the safe load on these springs, as we take one or the other coefficient,

J. W. Cloud (Trans. A. S. M. E., v. 173) gives the following:

$$P = \frac{S\pi d^3}{16R} \quad \text{and} \quad f = \frac{32PR^3l}{G\pi d^4};$$

- $P$  = load on spring;
- $S$  = maximum shearing fibre-strain in bar;
- $d$  = diameter of steel of which spring is made;
- $R$  = radius of centre of coil;
- $l$  = length of bar before coiling;
- $G$  = modulus of shearing elasticity;
- $f$  = deflection of spring under load.

Mr. Cloud takes  $S = 80,000$  and  $G = 12,600,000$ .

The stress in a helical spring is almost wholly one of torsion. For method of deriving the formulæ for springs from torsional formula see Mr. Cloud's paper, above quoted.

**PHOSPHOR-BRONZE SPRINGS.**

Wilfred Lewis (Engineers' Club, Philadelphia, 1887) made some tests with phosphor-bronze wire, .12 in. diameter, coiled in the form of a spiral spring, 1<sup>1</sup>/<sub>4</sub> in. diameter from centre to centre, making 52 coils.

Such a spring of steel, according to the practice of the P. R. R., might be used for 40 lbs. A load of 30 lbs. gradually applied gave a permanent set. With a load of 21 lbs. in 30 hours the spring lengthened from 20<sup>5</sup>/<sub>8</sub> inches to 21<sup>1</sup>/<sub>8</sub> inches, and in 200 hours to 21<sup>1</sup>/<sub>4</sub> inches. It was concluded that 21 lbs. was too great for durability. For a given load the extension of the bronze spring was just double the extension of a similar steel spring, that is, for the same extension the steel spring is twice as strong.

**SPRINGS TO RESIST TORSIONAL FORCE.**  
 (Reuleaux's Constructor.)

$$\begin{aligned} \text{Flat spiral or helical spring... } P &= \frac{Sbh^2}{6R}; & f = R\vartheta &= 12 \frac{PlR^2}{Ebkh^3}. \\ \text{Round helical spring ..... } P &= \frac{S\pi d^3}{32R}; & f = R\vartheta &= \frac{64PlR^2}{\pi E d^4}. \\ \text{Round bar, in torsion..... } P &= \frac{S\pi d^3}{16R}; & f = R\vartheta &= \frac{32P}{\pi G} \frac{R^2l}{d^4}. \\ \text{Flat bar, in torsion..... } P &= \frac{S}{3R} \frac{b^2h^2}{\sqrt{b^2 + h^2}}; & f = R\vartheta &= \frac{3Pk^2l}{G} \frac{b^2 + h^2}{b^3h^3}. \end{aligned}$$

P = force applied at end of radius or lever-arm R;  $\vartheta$  = angular motion at end of radius R; S = permissible maximum stress, = 4/5 of permissible stress in flexure; E = modulus of elasticity in tension; G = torsional modulus, = 2/5 E; l = developed length of spiral, or length of bar; d = diameter of wire; b = breadth of flat bar; h = thickness.

## RIVETED JOINTS.

**Fairbairn's Experiments.** (From Report of Committee on Riveted Joints, *Proc. Inst. M. E.*, April, 1881.)

The earliest published experiments on riveted joints are contained in the memoir by Sir W. Fairbairn in the Transactions of the Royal Society. Making certain empirical allowances, he adopted the following ratios as expressing the relative strength of riveted joints :

Solid plate.....	100
Double-riveted joint ....	70
Single-riveted joint.....	56

These well-known ratios are quoted in most treatises on riveting, and are still sometimes referred to as having a considerable authority. It is singular, however, that Sir W. Fairbairn does not appear to have been aware that the proportion of metal punched out in the line of fracture ought to be different in properly designed double and single riveted joints. These celebrated ratios would therefore appear to rest on a very unsatisfactory analysis of the experiments on which they were based.

**Loss of Strength in Punched Plates.**—A report by Mr. W. Parker and Mr. John, made in 1878 to Lloyd's Committee, on the effect of punching and drilling, showed that thin steel plates lost comparatively little from punching, but that in thick plates the loss was very considerable. The following table gives the results for plates punched and not annealed or reamed :

Thickness of Plates.	Material of Plates.	Loss of Tenacity, per cent.
$\frac{1}{4}$	Steel	8
$\frac{3}{8}$	"	18
$\frac{1}{2}$	"	26
$\frac{3}{4}$	"	33
$\frac{3}{4}$	Iron	18 to 23

The effect of increasing the size of the hole in the die-block is shown in the following table :

Total Taper of Hole in Plate, inches.	Material of Plates.	Loss of Tenacity due to Punching, per cent.
1-16	Steel	17.8.
$\frac{1}{8}$	"	12.3
$\frac{1}{4}$	"	(Hole ragged) 24.5

The plates were from 0.675 to 0.712 inch thick. When  $\frac{3}{8}$ -in. punched holes were reamed out to  $1\frac{1}{8}$  in. diameter, the loss of tenacity disappeared, and the plates carried as high a stress as drilled plates. Annealing also restores to punched plates their original tenacity.

**Strength of Perforated Plates.**

(P. D. Bennett, *Eng'g*, Feb. 12, 1886, p. 155.)

Tests were made to determine the relative effect produced upon tensile strength of a flat bar of iron or steel : 1. By a  $\frac{3}{4}$ -inch hole drilled to the required size ; 2. by a hole punched  $\frac{1}{8}$  inch smaller and then drilled to the size of the first hole ; and, 3, by a hole punched in the bar to the size of the drilled bar. The relative results in strength per square inch of original area were as follows :

	1.	2.	3.	4.
	Iron.	Iron.	Steel.	Steel.
Unperforated bar.....	1.000	1.000	1.000	1.000
Perforated by drilling.....	1.029	1.012	1.068	1.103
"    " punching and drilling.	1.030	1.008	1.059	1.110
"    " punching only .....	0.795	0.894	0.935	0.927

In tests 2 and 4 the holes were filled with rivets driven by hydraulic pressure. The increase of strength per square inch caused by drilling is a phenomenon of similar nature to that of the increased strength of a grooved bar over that of a straight bar of sectional area equal to the smallest section of the grooved bar. Mr. Bennett's tests on an iron bar 0.84 in. diameter, 10 in.

long, and a similar bar turned to 0.84 in. diameter at one point only, showed that the relative strength of the latter to the former was 1.323 to 1.000.

**Riveted Joints.—Drilling versus Punching of Holes.**

The Report of the Research Committee of the Institution of Mechanical Engineers, on Riveted Joints (1881), and records of investigations by Prof. A. B. W. Kennedy (1881, 1882, and 1885), summarize the existing information regarding the comparative effects of punching and drilling upon iron and steel plates. From an examination of the voluminous tables given in Professor Unwin's Report, the results of the greatest number of the experiments made on iron and steel plates lead to the general conclusion that, while thin plates, even of steel, do not suffer very much from punching, yet in those of 1/2-inch thickness and upwards the loss of tenacity due to punching ranges from 10% to 23% in iron plates, and from 11% to 33% in the case of mild steel. In drilled plates there is no appreciable loss of strength. It is possible to remove the bad effects of punching by subsequent reaming or annealing; but the speed at which work is turned out in these days is not favorable to multiplied operations, and such additional treatment is seldom practised. The introduction of a practicable method of drilling the plating of ships and other structures, after it has been bent and shaped, is a matter of great importance. If even a portion of the deterioration of tenacity can be prevented, a much stronger structure results from the same material and the same scantling. This has been fully recognized in the modern English practice (1887) of the construction of steam-boilers with steel plates; punching in such cases being almost entirely abolished, and all rivet-holes being drilled after the plates have been bent to the desired form.

**Comparative Efficiency of Riveting done by Different Methods.**

The Reports of Professors Unwin and Kennedy to the Institution of Mechanical Engineers (*Proc.* 1881, 1882, and 1885) tend to establish the four following points:

1. That the shearing resistance of rivets is not highest in joints riveted by means of the greatest pressure;
2. That the ultimate strength of joints is not affected to an appreciable extent by the mode of riveting; and, therefore,
3. That very great pressure upon the rivets in riveting is not the indispensable requirement that it has been sometimes supposed to be;
4. That the most serious defect of hand-riveted as compared with machine-riveted work consists in the fact that in hand-riveted joints visible slip commences at a comparatively small load, thus giving such joints a low value as regards tightness, and possibly also rendering them liable to failure under sudden strains after slip has once commenced.

The following figures of mean results, taken from Prof. Kennedy's tables (*Proceedings* 1885, pp. 218-225), give a comparative view of hand and hydraulic riveting, as regards their ultimate strengths in joints, and the periods at which in both cases visible slip commenced.

Total Breaking Load.		Load at which Visible Slip began.	
Hand-riveting.	Hydraulic Riveting.	Hand-riveting.	Hydraulic Riveting.
Tons.	Tons.	Tons.	Tons.
86.01	85.75	21.7	47.5
.....	77.00	....	35.0
82.16	82.70	25.0	53.7
.....	78.58	...	51.0
149.2	145.5	31.7	49.7
.....	140.2	....	46.7
193.3	183.1	25.0	56.0
.....	183.7	....	....

In these figures hand-riveting appears to be rather better than hydraulic riveting, as far as regards ultimate strength of joint; but is very much inferior to hydraulic work, in view of the small proportion of load borne by it before visible slip commenced,

**Some of the Conclusions of the Committee of Research on Riveted Joints.**

(*Proc. Inst. M. E., Apl. 1885.*)

The conclusions all refer to joints made in soft steel plate with steel rivets, the holes all drilled, and the plates in their natural state (unannealed). In every case the rivet or shearing area has been assumed to be that of the holes, not the nominal (or real) area of the rivets themselves. Also, the strength of the metal in the joint has been compared with that of strips cut from the same plates, and not merely with nominally similar material.

The metal between the rivet-holes has a considerably greater tensile resistance per square inch than the unperforated metal. This excess tenacity amounted to more than 20%, both in  $\frac{3}{8}$ -inch and  $\frac{3}{4}$ -inch plates, when the pitch of the rivet was about 1.9 diameters. In other cases  $\frac{3}{8}$ -inch plate gave an excess of 15% at fracture with a pitch of 2 diameters, of 10% with a pitch of 3.6 diameters, and of 6.6%, with a pitch of 3.9 diameters; and  $\frac{3}{4}$ -inch plate gave 7.8% excess with a pitch of 2.8 diameters.

In single-riveted joints it may be taken that about 22 tons per square inch is the shearing resistance of rivet steel, when the pressure on the rivets does not exceed about 40 tons per square inch. In double-riveted joints, with rivets of about  $\frac{3}{4}$  inch diameter, most of the experiments gave about 24 tons per square inch as the shearing resistance, but the joints in one series went at 22 tons.

The ratio of shearing resistance to tenacity is not constant, but diminishes very markedly and not very irregularly as the tenacity increases.

The size of the rivet heads and ends plays a most important part in the strength of the joints—at any rate in the case of single-riveted joints. An increase of about one third in the weight of the rivets (all this increase, of course, going to the heads and ends) was found to add about 8½% to the resistance of the joint, the plates remaining unbroken at the full shearing resistance of 22 tons per square inch, instead of tearing at a shearing stress of only a little over 20 tons. The additional strength is probably due to the prevention of the distortion of the plates by the great tensile stress in the rivets.

The intensity of bearing pressure on the rivet exercises, with joints proportioned in the ordinary way, a very important influence on their strength. So long as it does not exceed 40 tons per square inch (measured on the projected area of the rivets), it does not seem to affect their strength; but pressures of 50 to 55 tons per square inch seem to cause the rivets to shear in most cases at stresses varying from 16 to 18 tons per square inch. For ordinary joints, which are to be made equally strong in plate and in rivets, the bearing pressure should therefore probably not exceed 42 or 43 tons per square inch. For double-riveted butt-joints perhaps, as will be noted later, a higher pressure may be allowed, as the shearing stress may probably not be more than 16 or 18 tons per square inch when the plate tears.

A margin (or net distance from outside of holes to edge of plate) equal to the diameter of the drilled hole has been found sufficient in all cases hitherto tried.

To attain the maximum strength of a joint, the breadth of lap must be such as to prevent it from breaking zigzag. It has been found that the net metal measured zigzag should be from 30% to 35% in excess of that measured straight across, in order to insure a straight fracture. This corresponds to a diagonal pitch of  $\frac{2}{3}p + \frac{d}{3}$ , if  $p$  be the straight pitch and  $d$  the diameter of the rivet-hole.

Visible slip or "give" occurs always in a riveted joint at a point very much below its breaking load, and by no means proportional to that load. A collation of the results obtained in measuring the slip indicates that it depends upon the number and size of the rivets in the joint, rather than upon anything else; and that it is tolerably constant for a given size of rivet in a given type of joint. The loads per rivet at which a joint will commence to slip visibly are approximately as follows:

Diameter of Rivet.	Type of Joint.	Riveting.	Slipping Load per Rivet.
$\frac{3}{4}$ inch	Single-riveted	Hand	2.5 tons
$\frac{3}{4}$ "	Double-riveted	Hand	3.0 to 3.5 tons
$\frac{3}{4}$ "	Double-riveted	Machine	7 tons
1 inch	Single-riveted	Hand	3.2 tons
1 "	Double-riveted	Hand	4.3 tons
1 "	Double-riveted	Machine	8 to 10 tons

To find the probable load at which a joint of any breadth will commence to slip, multiply the number of rivets in the given breadth by the proper figure taken from the last column of the table above. It will be understood that the above figures are not given as exact; but they represent very well the results of the experiments.

The experiments point to simple rules for the proportioning of joints of maximum strength. Assuming that a bearing pressure of 43 tons per square inch may be allowed on the rivet, and that the excess tenacity of the plate is 10% of its original strength, the following table gives the values of the ratios of diameter  $d$  of hole to thickness  $t$  of plate ( $d + t$ ), and of pitch  $p$  to diameter of hole ( $p \div d$ ) in joints of maximum strength in  $\frac{3}{8}$ -inch plate.

**For Single-riveted Plates.**

Original Tenacity of Plate.		Shearing Resistance of Rivets.		Ratio. $d \div t$	Ratio. $p \div d$	Ratio. $\frac{\text{Plate Area}}{\text{Rivet Area}}$
Tons per sq. in.	Lbs. per sq. in.	Tons per sq. in.	Lbs. per sq. in.			
30	67,200	22	49,200	2.48	2.30	0.667
28	62,720	22	49,200	2.48	2.40	0.785
30	67,200	24	53,760	2.28	2.27	0.713
28	62,720	24	53,760	2.28	2.36	0.690

This table shows that the diameter of the hole (not the diameter of the rivet) should be  $2\frac{3}{8}$  times the thickness of the plate, and the pitch of the rivets  $2\frac{3}{8}$  times the diameter of the hole. Also, it makes the mean plate area 71% of the rivet area.

If a smaller rivet be used than that here specified, the joint will not be of uniform, and therefore not of maximum, strength; but with any other size of rivet the best result will be got by use of the pitch obtained from the simple formula

$$p = a \frac{d^2}{t} + d,$$

where, as before,  $d$  is the diameter of the hole.

The value of the constant  $a$  in this equation is as follows:

For 30-ton plate and 22-ton rivets,	$a = 0.524$
“ 28 “ “ 22 “ “	0.558
“ 30 “ “ 24 “ “	0.570
“ 28 “ “ 24 “ “	0.606

Or, in the mean, the pitch  $p = 0.56 \frac{d^2}{t} + d$ .

It should be noticed that with too small rivets this gives pitches often considerably smaller in proportion than  $2\frac{3}{8}$  times the diameter.

**For double-riveted lap-joints** a similar calculation to that given above, but with a somewhat smaller allowance for excess tenacity, on account of the large distance between the rivet-holes, shows that for joints of maximum strength the ratio of diameter to thickness should remain precisely as in single-riveted joints; while the ratio of pitch to diameter of hole should be 3.64 for 30-ton plates and 22 or 24 ton rivets, and 3.82 for 28-ton plates with the same rivets.

Here, still more than in the former case, it is likely that the prescribed size of rivet may often be inconveniently large. In this case the diameter of rivet should be taken as large as possible; and the strongest joint for a given thickness of plate and diameter of hole can then be obtained by using the pitch given by the equation

$$p = a \frac{d^2}{t} + d,$$

where the values of the constant  $a$  for different strengths of plates and rivets may be taken as follows:

**Table of Proportions of Double-riveted Lap-joints,**

$$\text{in which } p = a \frac{d^2}{t} + d.$$

Thickness of Plate.	Original tenacity of Plate, Tons per sq. in.	Shearing Resistance of Rivets, Tons per sq. in.	Value of Constant, $a$
$\frac{3}{8}$ inch	30	24	1.15
$\frac{3}{8}$ "	28	24	1.22
$\frac{3}{8}$ "	30	22	1.05
$\frac{3}{8}$ "	28	22	1.12
$\frac{3}{4}$ "	30	24	1.17
$\frac{3}{4}$ "	28	24	1.25
$\frac{3}{4}$ "	30	22	1.07
$\frac{3}{4}$ "	28	23	1.14

Practically, having assumed the rivet diameter as large as possible, we can fix the pitch as follows. for any thickness of plate from  $\frac{3}{8}$  to  $\frac{3}{4}$  inch:

$$\begin{aligned} \text{For 30-ton plate and 24-ton rivets } \left\{ \begin{aligned} p &= 1.16 \frac{d^2}{t} + d; \\ \text{" 28 " " " 22 " " } & \\ \text{" 30 " " " 22 " " } & p = 1.06 \frac{d^2}{t} + d; \\ \text{" 28 " " " 24 " " } & p = 1.24 \frac{d^2}{t} + d. \end{aligned} \right. \end{aligned}$$

**In double-riveted butt-joints** it is impossible to develop the full shearing resistance of the joint without getting excessive bearing pressure, because the shearing area is doubled without increasing the area on which the pressure acts. Considering only the plate resistance and the bearing pressure, and taking this latter as 45 tons per square inch, the best pitch would be about 4 times the diameter of the hole. We may probably say with some certainty that a pressure of from 45 to 50 tons per square inch on the rivets will cause shearing to take place at from 16 to 18 tons per square inch. Working out the equations as before, but allowing excess strength of only 5% on account of the large pitch, we find that the proportions of double-riveted butt-joints of maximum strength, under given conditions, are those of the following table:

**Double-riveted Butt-joints.**

Original Tenacity of Plate, Tons per sq. in.	Shearing Resistance of Rivets, Tons per sq. in.	Bearing Pressure, Tons per sq. in.	Ratio $\frac{d}{t}$	Ratio $\frac{p}{d}$
30	16	45	1.80	3.85
28	16	45	1.80	4.06
30	18	48	1.70	4.03
28	18	48	1.70	4.27
30	16	50	2.00	4.20
28	16	50	2.00	4.42

Practically, therefore, it may be said that we get a double-riveted butt-joint of maximum strength by making the diameter of hole about 1.8 times the thickness of the plate, and making the pitch 4.1 times the diameter of the hole.

The proportions just given belong to joints of maximum strength. But in a boiler the one part of the joint, the plate, is much more affected by time than the other part, the rivets. It is therefore not unreasonable to estimate the percentage by which the plates might be weakened by corrosion, etc., before the boiler would be unfit for use at its proper steam-pressure, and to add correspondingly to the plate area. Probably the best thing to do in this case is to proportion the joint, not for the actual thickness of plate, but for a nominal thickness less than the actual by the assumed percentage. In this case the joint will be approximately one of uniform strength by the time it has reached its final workable condition; up to which time the joint as a whole will not really have been weakened, the corrosion only gradually bringing the strength of the plates down to that of rivets.

**Efficiencies of Joints.**

The average results of experiments by the committee gave: For double-riveted lap-joints in  $\frac{3}{8}$ -inch plates, efficiencies ranging from 67.1% to 81.2%. For double-riveted butt-joints (in double shear) 61.4% to 71.3%. These low results were probably due to the use of very soft steel in the rivets. For single-riveted lap-joints of various dimensions the efficiencies varied from 54.8% to 60.8%.

The experiments showed that the shearing resistance of steel did not increase nearly so fast as its tensile resistance. With very soft steel, for instance, of only 26 tons tenacity, the shearing resistance was about 80% of the tensile resistance, whereas with very hard steel of 52 tons tenacity the shearing resistance was only somewhere about 65% of the tensile resistance.

**Proportions of Pitch and Overlap of Plates to Diameter of Rivet-Hole and Thickness of Plate.**

(Prof. A. B. W. Kennedy, *Proc. Inst. M. E.*, April, 1885.)

- $t$  = thickness of plate;
- $d$  = diameter of rivet (actual) in parallel hole;
- $p$  = pitch of rivets, centre to centre;
- $s$  = space between lines of rivets;
- $l$  = overlap of plate.

The pitch is as wide as is allowable without impairing the tightness of the joint under steam.

For single-riveted lap-joints in the circular seams of boilers which have double-riveted longitudinal lap joints,

$$\begin{aligned} d &= t \times 2.25; \\ p &= d \times 2.25 = t \times 5 \text{ (nearly);} \\ l &= t \times 6. \end{aligned}$$

For double-riveted lap-joints:

$$\begin{aligned} d &= 2.25t; \\ p &= 8t; \\ s &= 4.5t; \\ l &= 10.5t. \end{aligned}$$

Single-riveted Joints.				Double-riveted Joints.				
$t$	$d$	$p$	$l$	$t$	$d$	$p$	$s$	$l$
3-16	7-16	15-16	$1\frac{1}{8}$	3-16	7-16	$1\frac{1}{2}$	$\frac{7}{8}$	2
$\frac{1}{4}$	9-16	$1\frac{1}{4}$	$1\frac{1}{2}$	$\frac{1}{4}$	9-16	2	1 3-16	$2\frac{3}{4}$
5-16	11-16	1 9-16	$1\frac{7}{8}$	5-16	11-16	$2\frac{1}{2}$	$1\frac{1}{2}$	$3\frac{3}{8}$
$\frac{3}{8}$	13-16	$1\frac{7}{8}$	$2\frac{1}{4}$	$\frac{3}{8}$	13-16	3	$1\frac{3}{4}$	4
7-16	1	2 3-16	$2\frac{5}{8}$	7-16	1	$3\frac{1}{2}$	2	$4\frac{5}{8}$
$\frac{1}{2}$	$1\frac{1}{8}$	$2\frac{1}{2}$	3	$\frac{1}{2}$	$1\frac{1}{8}$	4	$2\frac{1}{4}$	$5\frac{1}{4}$
9-16	$1\frac{1}{4}$	2 13-16	$3\frac{3}{8}$	9-16	$1\frac{1}{4}$	$4\frac{1}{2}$	$2\frac{1}{2}$	$5\frac{7}{8}$

With these proportions and good workmanship there need be no fear of leakage of steam through the riveted joint.

The net diagonal area, or area of plate, along a zigzag line of fracture should not be less than 30% in excess of the net area straight across the joint, and 35% is better.

Mr. Theodore Cooper (*R. R. Gazette*, Aug. 22, 1890) referring to Prof. Kennedy's statement quoted above, gives as a sufficiently approximate rule for the proper pitch between the rows in staggered riveting, one half of the pitch of the rivets in a row plus one quarter the diameter of a rivet-hole.

**Apparent Excess in Strength of Perforated over Unperforated Plates.** (*Proc. Inst. M. E.*, October, 1888.)

The metal between the rivet-holes has a considerably greater tensile resistance per square inch than the unperforated metal. This excess tenacity amounted to more than 20%, both in  $\frac{3}{8}$ -inch and  $\frac{3}{4}$ -inch plates, when the pitch of the rivets was about 1.9 diameters. In other cases  $\frac{3}{8}$ -inch plate gave an excess of 15% at fracture with a pitch of 2 diameters, of 10% with a pitch of 3.6 diameters, and of 6.6% with a pitch of 3.9 diameters; and  $\frac{3}{4}$ -inch plate gave 7.8% excess with a pitch of 2.8 diameters.

(1) The "excess strength due to perforation" is increased by anything which tends to make the stress in the plate uniform, and to diminish the effect of the narrow strip of metal at the edge of the specimen.

(2) It is diminished by increase in the ratio of  $p/d$ , of pitch to diameter of hole, so that in this respect it becomes less as the efficiency of the joint increases.

(3) It is diminished by any increase in hardness of the plate.

(4) For a given ratio  $p/d$ , of pitch to diameter of hole, it is also apparently diminished as the thickness of the plate is increased. The ratio of pitch to thickness of plate does not seem to affect this matter directly, at least within the limits of the experiments.

**Test of Double-riveted Lap and Butt Joints.**

(Proc. Inst. M. E., October, 1888.)

Steel plates of 25 to 26 tons per square inch T. S., steel rivets of 24.6 tons shearing-strength per square inch.

**Strength of Double-riveted Seams, Calculated.**—W. B. Ruggles, Jr., in *Power* for June, 1890, gives tables of relative strength of rivets and parts of sheet between rivets in double-riveted seams, compared with strength of shell, based on the assumption that the shearing strength of rivets and the tensile strength of steel are equal. The following figures show the sizes in his tables which show the nearest approximation to equality of strength of rivets and parts of plates between the rivets, together with the percentage of each relative to the strength of the solid plate.

Thickness of plate, inches.	Pitch of Rivets, inches.	Size of Rivet-holes, inches.	Percentage of Strength of Plate.		Thickness of Plate, inches.	Pitch of Rivets, inches.	Size of Rivet-holes, inches.	Percentage of Strength of Plate.

H. De B. Parsons (*Am. Engr. & R. R. Jour.*, 1893) holds that it is an error to assume that the shearing strength of the rivet is equal to the tensile strength. Also, referring to the apparent excess in strength of perforated over unperforated plates, he claims that on account of the difficulty in properly matching the holes, and of the stress caused by forcing, as is too often the case in practice, this additional strength cannot be trusted much more than that of friction.

Adopting the sizes of iron rivets as generally used in American practice for steel plates from 1/4 to 1 inch thick: the tensile strength of the plates as 60,000 lbs.; the shearing strength of the rivets as 40,000 for single-shear and 35,500 for double-shear, Mr. Parsons calculates the following table of pitches, so that the strength of the rivets against shearing will be approximately equal to that of the plate to tear between rivet-holes. The diameter of the rivets has in all cases been taken at 1/16 in. larger than the nominal size, as the rivet is assumed to fill the hole under the power riveter.

**Riveted Joints.**

**LAP OR BUTT WITH SINGLE WELT—STEEL PLATES AND IRON RIVETS.**

1	1 1/8	2 3/16	2 5/8	38.1	54.9

**Calculated Efficiencies—Steel Plates and Steel Rivets.—**

The differences between the calculated efficiencies given in the two tables above are notable. Those given by Mr. Ruggles are probably too high, since he assumes the shearing strength of the rivets equal to the tensile strength of the plates. Those given by Mr. Parsons are probably lower than will be obtained in practice, since the figure he adopts for shearing strength is rather low, and he makes no allowance for excess of strength of the perforated over the unperforated plate. The following table has been calculated by the author on the assumptions that the excess strength of the perforated plate is 10%, and that the shearing strength of the rivets per square inch is four fifths of the tensile strength of the plate. If  $t$  = thickness of plate,  $d$  = diameter of rivet-hole,  $p$  = pitch, and  $T$  = tensile strength per square inch, then for single-riveted plates

$$(p - d)t \times 1.10T = \frac{\pi}{4}d^2 \times \frac{4}{5}T, \text{ whence } p = .571\frac{d^2}{t} + d.$$

$$\text{For double-riveted plates, } p = 1.142\frac{d^2}{t} + d.$$

The coefficients .571 and 1.142 agree closely with the averages of those given in the report of the committee of the Institution of Mechanical Engineers, quoted on pages 357 and 358, *ante*.

**Riveting Pressure Required for Bridge and Boiler Work.**

(Wilfred Lewis, Engineers' Club of Philadelphia, Nov., 1893.)

A number of 3/8-inch rivets were subjected to pressures between 10,000 and 60,000 lbs. At 10,000 lbs. the rivet swelled and filled the hole without forming a head. At 20,000 lbs. the head was formed and the plates were slightly pinched. At 30,000 lbs. the rivet was well set. At 40,000 lbs. the metal in the plate surrounding the rivet began to stretch, and the stretching became more and more apparent as the pressure was increased to 50,000 and 60,000 lbs. From these experiments the conclusion might be drawn that the pressure required for cold riveting was about 300,000 lbs. per square inch of rivet section. In hot riveting, until recently there was never any call for a pressure exceeding 60,000 lbs., but now pressures as high as 150,000 lbs. are not uncommon, and even 300,000 lbs. have been contemplated as desirable.

**Apparent Shearing Resistance of Rivet Iron and Steel.**

(*Proc. Inst. M. E., 1879, Engineering, Feb. 20, 1880.*)

The true shearing resistance of the rivets cannot be ascertained from experiments on riveted joints (1) because the uniform distribution of the load to all the rivets cannot be insured; (2) because of the friction of the plates, which has the effect of increasing the apparent resistance to shearing in an element uncertain in amount. Probably in the case of single-riveted joints the shearing resistance is not much affected by the friction.

	Ultimate Shearing Stress		
	Tons per sq. in.	Lbs. per sq. in.

" double shear (8 bars)..	22.10	49.504	
" " " ..	22.62	50.669	} Barnaby.
" " " ..	22.30	49.952	
" 3/4-in. rivets.....	23.05 to 25.57	51.632 to 57.277	} Riley.
" 5/8-in. rivets.....	24.32 to 27.94	54.477 to 62.362	
" mean value .....	25.0	56.000	
" 5/8-in. rivets. ....	19.01	42.582	Greig and Eyth.
Steel .....	17 to 26	38.080 to 58.240	Parker.
Landore steel, 3/4-in. rivets..	31.67 to 33.69	70.941 to 75.466	} Riley.
" " 5/8-in. rivets..	30.45 to 35.73	68.208 to 80.035	
" " mean value..	33.3	74.592	
Brown's steel.....	23.18	49.683	Greig and Eyth.

Fairbairn's experiments show that a rivet is 61 1/2% weaker in a drilled than in a punched hole. By rounding the edge of the rivet-hole the apparent shearing resistance is increased 12%. Mr. Maynard found the rivets 4% weaker in drilled holes than in punched holes. But these results were obtained with riveted joints, and not by direct experiments on shearing. There is a good deal of difficulty in determining the true diameter of a punched hole, and it is doubtful whether in these experiments the diameter was very accurately ascertained. Messrs. Greig and Eyth's experiments also indicate a greater resistance of the rivets in punched holes than in drilled holes.

If, as appears above, the apparent shearing resistance is less for double than for single shear, it is probably due to unequal distribution of the stress on the two rivet sections.

The shearing resistance of a bar, when sheared in circumstances which prevent friction, is usually less than the tenacity of the bar. The following results show the decrease :

	Tenacity of Bar.	Shearing Resistance.	Ratio.
Harkort, iron.....	26.4	16.5	0.62
Lavalley, iron.....	25.4	20.2	0.79
Greig and Eyth, iron...	22.2	19.0	0.85
" " steel..	28.8	22.1	0.77

In Wöhler's researches (in 1870) the shearing strength of iron was found to be four-fifths of the tenacity. Later researches of Bauschinger confirm this result generally, but they show that for iron the ratio of the shearing resistance and tenacity depends on the direction of the stress relatively to the direction of rolling. The above ratio is valid only if the shear is in a plane perpendicular to the direction of rolling, and if the tension is applied parallel to the direction of rolling. The shearing resistance in a plane parallel to the direction of rolling is different from that in a plane perpendicular to that direction, and again differs according as the plane of shear is perpendicular or parallel to the breadth of the bar. In the former case the resistance is 18 to 20% greater than in a plane perpendicular to the fibres, or is equal to the tenacity. In the latter case it is only half as great as in a plane perpendicular to the fibres.

IRON AND STEEL.

CLASSIFICATION OF IRON AND STEEL.

CLASSIFICATION OF IRON AND STEEL.

(W. Kent, Railroad & Engineering Journal, April, 1887.)

IRON.																					
Generic Term.																					
How Obtained.	<i>CAST,</i> Or obtained from a fluid mass.																				
Distinguishing Quality.	<i>Non-malleable.</i>

<i>Non-malleable.</i>	<i>CAST IRON.</i>	<i>CAST STEEL.</i>	<i>WROUGHT,</i> Or welded from a pasty mass.																		
(1) Ordinary castings.	(2) Malleable cast iron, obtained from No. 1 by annealing in oxides.	(3) Crucible, (4) Bessemer, and (5) Open-hearth steels. (6) Mitis.*	<i>Will Not Harden.</i>																		
			<i>Will Harden.</i>																		
			(St) <i>WROUGHT STEEL.</i>																		
			Obtained by direct or indirect process, as German, shear, blister, and puddled steels.																		
			(7) <i>WROUGHT IRON.</i>																		
			<i>a.</i> Obtained by direct process from ores, as Catalan, Chenot, and other process irons. <i>b.</i> Obtained by indirect process from cast iron, as finery-hearth and puddled irons.																		

\* No. 6. Mitis is the name given to a new product (having the same general properties and produced by the same processes as soft cast steels) made by adding an alloy of aluminum to melted wrought iron or soft steel before pouring.  
 + No. 8. Wrought steel is almost an obsolete product, having been replaced in commerce by cast steel.  
 Sub-varieties of Nos. 3, 4, and 5, soft, mild, medium, and hard steels, according to percentage of carbon, the divisions between them not being well defined.  
 Cast iron usually contains over 3% of carbon; cast steel anywhere from 0.06% to 1.50%, according to the purpose for which it is used; wrought iron from 0.02% to 0.10%. The quality of hardening and tempering which formerly distinguished steel from wrought iron is now no longer the dividing line between them, since soft steels are now produced which, by the ordinary blacksmith's tests, will not harden. All products of the crucible, Bessemer, and open-hearth processes are now commercially known as steel.

## CAST IRON.

**Grading of Pig Iron.**—Pig iron is commonly graded according to its fracture, the number of grades varying in different districts. In Eastern Pennsylvania the principal grades recognized are known as No. 1 and 2 foundry, gray forge or No. 3, mottled or No. 4, and white or No. 5. Intermediate grades are sometimes made, as No. 2 X, between No. 1 and No. 2, and special names are given to irons more highly silicized than No. 1, as No. 1 X, silver-gray, and soft. Charcoal foundry pig iron is graded by numbers 1 to 5, but the quality is very different from the corresponding numbers in anthracite and coke pig. Southern coke pig iron is graded into ten or more grades. Grading by fracture is a fairly satisfactory method of grading irons made from uniform ore mixtures and fuel, but is unreliable as a means of determining quality of irons produced in different sections or from different ores. Grading by chemical analysis, in the latter case, is the only satisfactory method. The following analyses of the five standard grades of northern foundry and mill pig irons are given by J. M. Hartman (*Bull. I. & S. A.*, Feb., 1892):

	No. 1.	No. 2.	No. 3.	No. 4.	No. 4 B.	No. 5.
Iron .....	92.37	92.31	94.66	94.48	94.08	94.68
Graphitic carbon ..	3.52	2.99	2.50	2.02	2.02	.....
Combined carbon..	.13	.37	1.52	1.98	1.43	3.83
Silicon .....	2.44	2.52	.72	.56	.92	.41
Phosphorus ....	1.25	1.08	.26	.19	.04	.04
Sulphur .....	.02	.02	trace	.08	.04	.02
Manganese.....	.28	.72	.34	.67	2.02	.98

## CHARACTERISTICS OF THESE IRONS.

No. 1. *Gray*.—A large, dark, open-grain iron, softest of all the numbers and used exclusively in the foundry. Tensile strength low. Elastic limit low. Fracture rough. Turns soft and tough.

No. 2. *Gray*.—A mixed large and small dark grain, harder than No. 1 iron, and used exclusively in the foundry. Tensile strength and elastic limit higher than No. 1. Fracture less rough than No. 1. Turns harder, less tough, and more brittle than No. 1.

No. 3. *Gray*.—Small, gray, close grain, harder than No. 2 iron, used either in the rolling-mill or foundry. Tensile strength and elastic limit higher than No. 2. Turns hard, less tough, and more brittle than No. 2.

No. 4. *Mottled*.—White background, dotted closely with small black spots of graphitic carbon; little or no grain. Used exclusively in the rolling-mill. Tensile strength and elastic limit lower than No. 3. Turns with difficulty; less tough and more brittle than No. 3. The manganese in the B pig iron replaces part of the combined carbon, making the iron harder and closing the grain, notwithstanding the lower combined carbon.

No. 5. *White*.—Smooth, white fracture, no grain, used exclusively in the rolling mill. Tensile strength and elastic limit much lower than No. 4. Too hard to turn and more brittle than No. 4.

Southern pig irons are graded as follows, beginning with the highest in silicon: Nos. 1 and 2 silvery, Nos. 1 and 2 soft, all containing over 3% of silicon; Nos. 1, 2, and 3 foundry, respectively about 2.75%, 2.5% and 2% silicon; No. 1 mill, or "foundry forge;" No. 2 mill, or gray forge; mottled; white.

Good charcoal chilling iron for car wheels contains, as a rule, 0.56 to 0.95 silicon, 0.08 to 0.90 manganese, 0.05 to 0.75 phosphorus. The following is an analysis of a remarkably strong car wheel: Si, 0.734; Mn, 0.438; P, 0.428, S, 0.08; Graphitic C, 3.083; Combined C, 1.247; Copper, 0.029. The chill was very hard— $\frac{1}{4}$  in. deep at root of flange,  $\frac{1}{2}$  in. deep on tread. A good ordnance iron analyzed: Si, 0.30; Graphitic C, 2.20; Combined C, 1.70; P, 0.44; Mn, 3.55 (?). Its specific gravity was 7.22 and tenacity 31,734 lbs. per sq. in.

**Influence of Silicon, Phosphorus, Sulphur, and Manganese upon Cast Iron.**—W. J. Keep, of Detroit, in several papers (*Trans. A. I. M. E.*, 1889 to 1893), discusses the influence of various chemical elements on the quality of cast iron. From these the following notes have been condensed:

**SILICON.**—Pig iron contains all the carbon that it could absorb during its reduction in the blast-furnace. Carbon exists in cast iron in two distinct forms. In chemical union, as "combined" carbon, it cannot be discerned, except as it may increase the whiteness of the fracture, in so-called white

iron. Carbon mechanically mixed with the iron as graphite is visible, varying in color from gray to black, while the fracture of the iron ranges from a light to a very dark gray.

Silicon will expel carbon, if the iron, when melted, contains all the carbon that it can hold and a portion of silicon be added.

Prof. Turner concludes from his tests that the amount of silicon producing the maximum strength is about 1.80%. But this is only true when a white base is used. If an iron is used as a base which will produce a sound casting to begin with, each addition of silicon will decrease strength. Silicon itself is a weakening agent. Variations in the percentage of silicon added to a pig iron will not insure a given strength or physical structure, but these results will depend upon the physical properties of the original iron.

After enough silicon has been added to cause solid castings, any further addition and consequent increase of graphite weakens the casting.

As strength decreases from increase of graphite and decrease of combined carbon, deflection increases; or, in other words, bending is increased by graphite. When no more graphite can form and silicon still increases, deflection diminishes, showing that high silicon not only weakens iron, but makes it stiff. This stiffness is not the same strength-stiffness which is caused by compact iron and combined carbon. It is a *brittle-stiffness*.

Silicon of itself, however small the quantity present, hardens cast-iron; but the decrease of hardness from the change of the combined carbon to graphite, caused by the silicon, is so much more rapid than the hardening produced by the increase of silicon, that the total effect is to decrease hardness, until the silicon reaches from 3 to 5%.

As practical foundry-work does not call for more than 3% of silicon, the ordinary use of silicon does reduce the hardness of castings; but this is produced through its influence on the carbon, and not its direct influence on the iron.

When the change from combined to graphite carbon has ceased to diminish hardness, say at from 2% to 5% of silicon, the hardening by the silicon itself becomes more and more apparent as the silicon increases.

The term "chilling" irons is generally applied to such as, cooled slowly, would be gray, but cooled suddenly become white either to a depth sufficient for practical utilization (*e.g.*, in car-wheels) or so far as to be detrimental. Many irons chill more or less in contact with the cold surface of the mould in which they are cast, especially if they are thin. Sometimes this is a valuable quality, but for general foundry purposes it is desirable to have all parts of a casting an even gray.

Silicon exerts a powerful influence upon this property of irons, partially or entirely removing their capacity of chilling.

When silicon is mixed with irons previously low in silicon the fluidity is increased.

It is not the percentage of silicon, but the state of the carbon and the action of silicon through other elements, which causes the iron to be fluid.

Silicon irons have always had the reputation of imparting fluidity to other irons. This comes, no doubt, from the fact that up to 3% or 4% they increase the quantity of graphite in the resulting casting.

A white iron which will invariably give porous and brittle castings can be made solid and strong by the addition of silicon; a further addition of silicon will turn the iron gray; and as the grayness increases the iron will grow weaker. Excessive silicon will again lighten the grain and cause a hard and brittle as well as a very weak iron. The only softening and shrinkage-lessening influence of silicon is exerted during the time when graphite is being produced, and silicon of itself is not a softener or a lessener of shrinkage; but through its influence on carbon, and only during a certain stage, does it produce these effects.

**PHOSPHORUS.**—While phosphorus of itself, in whatever quantity present, weakens cast-iron, yet in quantities less than 1.5% its influence is not sufficiently great to overbalance other beneficial effects, which are exerted before the percentage reaches 1%. Probably no element of itself weakens cast iron as much as phosphorus, especially when present in large quantities.

Shrinkage is decreased when phosphorus is increased. All high-phosphorus pig irons have low shrinkage. Phosphorus does not ordinarily harden cast iron, probably for the reason that it does not increase combined carbon.

The fluidity of the metal is slightly increased by phosphorus, but not to any such great extent as has been ascribed to it.

The property of remaining long in the fluid state must not be confounded with fluidity, for it is not the measure of its ability to make sharp castings,

or to run into the very thin parts of a mould. Generally speaking, the statement is justified that, to some extent, phosphorus prolongs the fluidity of the iron while it is filling the mould.

The old Scotch irons contained about 1% of phosphorus. The foundry-irons which are most sought for for small and thin castings in the Eastern States contain, as a general thing, over 1% of phosphorus.

Certain irons which contain from 4% to 7% silicon have been so much used on account of their ability to soften other irons that they have come to be known as "softeners" and as lesseners of shrinkage. These irons are valuable as carriers of silicon; but the irons which are sold most as softeners and shrinkage-lesseners are those containing from 1% to 2% of phosphorus. We must therefore ascribe the reputation of some of them largely to the phosphorus and not wholly to the silicon which they contain.

From  $\frac{1}{2}$ % to 1% of phosphorus will do all that can be done in a beneficial way, and all above that amount weakens the iron, without corresponding benefit. It is not necessary to search for phosphorus-irons. Most irons contain more than is needed, and the care should be to keep it within limits.

**SULPHUR.**—Only a small percentage of sulphur can be made to remain in carbonized iron, and it is difficult to introduce sulphur into gray cast iron or into any carbonized iron, although gray cast iron often takes from the fuel as much more sulphur as the iron originally contained. Percentages of sulphur that could be retained by gray cast iron cannot materially injure the iron except through an increase of shrinkage. The higher the carbon, or the higher the silicon, the smaller will be the influence exerted by sulphur.

The influence of sulphur on all cast iron is to drive out carbon and silicon and to increase chill, to increase shrinkage, and, as a general thing, to decrease strength; but if in practice sulphur will not enter such iron, we shall not have any cause to fear this tendency. In every-day work, however, it is found at times that iron which was gray when put into the cupola comes out white, with increased shrinkage and chill, and often with decreased strength. This is caused by decreased silicon, and can be remedied by an increase of silicon.

Mr. Keep's opinion concerning the influence of sulphur, quoted above, is disagreed with by J. B. Nau (*Iron Age*, March 29, 1894). He says:

"Sulphur, in whatever shape it may be present, has a deleterious influence on the iron. It has the tendency to render the iron white by the influence it exercises on the combination between carbon and iron. Pig iron containing a certain percentage of it becomes porous and full of holes, and castings made from sulphurous iron are of inferior quality. This happens especially when the element is present in notable quantities. With foundry-iron containing as high as 0.1% of sulphur, castings of greater strength may be obtained than when no sulphur is present.

That the sulphur contents of pig iron may be increased by the sulphur contained in the coke used, is shown by some experiments in the cupola, reported by Mr. Nau. Seven consecutive heats were made.

The sulphur content of the coke was 1%, and 11.7% of fuel was added to the charge.

Before melting, the silicon ranged from 0.320 to 0.830 in the seven heats; after melting, it was from 0.110 to 0.534, the loss in melting being from .100 to .375. The sulphur before melting was from .076 to .090, and after melting from .132 to .174, a gain from .044 to .098.

From the results the following conclusions were drawn:

1. In all the charges, without exception, sulphur increased in the pig iron after its passage through the cupola. In some cases this increase more than doubled the original amount of sulphur found in the pig iron.

2. The increase of the sulphur contents in the iron follows the elimination of a greater amount of silicon from that same iron. A larger amount of limestone added to these charges would have produced a more basic cinder, and undoubtedly less sulphur would have been incorporated in the iron.

3. This coke contained 1% of sulphur, and if all its sulphur had passed into the iron there would have been an average increase of 0.12 of sulphur for the seven charges, while the real increase in the pig iron amounted to only 0.081. This shows that two thirds of the sulphur of the coke was taken up by the iron in its passage through the cupola.

**MANGANESE.**—Manganese is a nearly white metal, having about the same appearance when fractured as white cast iron. As produced commercially, it is combined with iron, and with small percentages of silicon, phosphorus, and sulphur.

If the manganese is under 40%, with the remainder mostly iron, and silicon

not over 0.50%, the alloy is called spiegeleisen, and the fracture will show flat reflecting surfaces, from which it takes its name.

With manganese above 50%, the iron alloy is called ferro-manganese.

As manganese increases beyond 50%, the mass cracks in cooling, and when it approaches 98% the mass crumbles or falls in small pieces.

Manganese combines with iron in almost any proportion, but if an iron containing manganese is remelted, more or less of the manganese will escape by volatilization, and by oxidation with other elements present in the iron. If sulphur be present, some of the manganese will be likely to unite with it and escape, thus reducing the amount of both elements in the casting.

Cast iron, when free from manganese, cannot hold more than 4.50% of carbon, and 3.50% is as much as is generally present; but as manganese increases, carbon also increases, until we often find it in spiegel as high as 5%, and in ferro-manganese as high as 6%. This effect on capacity to hold carbon is peculiar to manganese.

Manganese renders cast iron less plastic and more brittle.

Manganese increases the shrinkage of cast iron. An increase of 1% raised the shrinkage 26%. Judging from some test records, manganese does not influence chill at all; but other tests show that with a given percentage of silicon the carbon may be a little more inclined to remain in the combined form, and therefore the chill may be a little deeper. Hence, to cause the chill to be the same, it would seem that the percentage of silicon should be a little higher with manganese than without it.

An increase of 1% of manganese increased the hardness 40%. If a hard chill is required, manganese gives it by adding hardness to the whole casting.

J. B. Nau (*Iron Age*, March 29, 1894), discussing the influence of manganese on cast iron, says:

Manganese favors the combination between carbon and iron. Its influence, when present in sufficiently large quantities, is even great enough not only to keep the carbon which would be naturally found in pig iron combined, but it increases the capacity of iron to retain larger amounts of carbon and to retain it all in the combined state.

Manganese iron is often used for foundry purposes when some chill and hardness of surface is required in the casting. For the rolls of steel-rail mills we always put into the mixture a large amount of manganiferous iron, and the rolls so obtained always presented the desired hardness of surface and in general a mottled structure on the outside. The inside, which always cooled much slower, was gray iron. One of the standard mixtures that invariably gave good results was the following:

50% of foundry iron with 1.3% silicon and 1.5% manganese;

35% of foundry iron with 1% silicon and 1.5% manganese;

15% steel (rail ends) with about 0.35% to 0.40% carbon.

The roll resulting from this mixture contained about 1% of silicon and 1% of manganese.

Another mixture, which differed but little from the preceding, was as follows:

45% foundry iron with about 1.3% silicon and 1.5% manganese;

30% foundry iron with about 1% silicon and 1.5% manganese;

10% white or mottled iron with about 0.5% to 0.6% Si. and 1.2% Mn.

15% Bessemer steel-rail ends with about 0.35% to 0.40% C. and 0.6% to 1% Mn.

The pig iron used in the preceding mixtures contained also invariably from 1.5% to 1.8% of phosphorus, so that the rolls obtained therefrom carried about 1.3% to 1.4% of that element. The last mixture used produced rolls containing on the average 0.8% to 1% of silicon and 1% of manganese. Whenever we tried to make those rolls from a mixture containing but 0.2% to 0.3% manganese our rolls were invariably of inferior quality, grayer, and consequently softer. Manganese iron cannot be used indiscriminately for foundry purposes. When greater softness is required in the castings manganese has to be avoided, but when hardness to a certain extent has to be obtained manganese iron can be used with advantage.

Manganese decreases the magnetism of the iron. This characteristic increases with the percentage of manganese that enters into the composition of the iron. The iron loses all its magnetism when manganese reaches 25% of its composition. For this reason manganese iron has to be avoided in castings of dynamo fields and other pieces belonging to electric machinery, where magnetic conductivity is one of the first considerations.

**Shrinkage of Cast Iron.**—Mr. Keep gives a series of curves showing that shrinkage depends on silicon and on the cross-section of the casting, decreasing as the silicon and the section increase. The following figures are obtained by inspection of the curves:

Silicon, Per Cent.	Size of Square Bars.					Silicon, Per Cent.	Size of Square Bars.				
	½ in.	1 in.	2 in.	3 in.	4 in.		½ in.	1 in.	2 in.	3 in.	4 in.
	Shrinkage, In. per Foot.						Shrinkage, In. per Foot.				
1.00	.178	.158	.129	.112	.102	2.50	.142	.121	.091	.072	.060
1.50	.166	.145	.116	.099	.088	3.00	.130	.109	.078	.058	.046
2.00	.154	.133	.104	.086	.074	3.50	.118	.097	.065	.045	.032

Mr. Keep says: "The measure of shrinkage is practically equivalent to a chemical analysis of silicon. It tells whether more or less silicon is needed to bring the quality of the casting to an accepted standard of excellence."

**Strength in Relation to Silicon and Cross-section.**—

In castings one half-inch square in section the strength increases as silicon increases from 1.00 to 3.50; in castings 1 in. square in section the strength is practically independent of silicon, while in larger castings the strength decreases as silicon increases.

The following table shows values taken from Mr. Keep's curves of the approximate transverse strength of ½-in. × 12-in. cast bars of different sizes.

Silicon, Per Cent.	Size of Square Cast Bars.					Silicon, Per Cent.	Size of Square Cast Bars.				
	½ in.	1 in.	2 in.	3 in.	4 in.		½ in.	1 in.	2 in.	3 in.	4 in.
	Strength of a ½-in. × 12-in. Section, lbs.						Strength of a ½-in. × 12-in. Section, lbs.				
1.00	290	260	232	222	220	2.50	392	278	212	190	184
1.50	324	272	228	212	208	3.00	426	276	202	180	172
2.00	358	278	220	202	196	3.50	446	264	192	168	160

**Irregular Distribution of Silicon in Pig Iron.**—J. W.

Thomas (*Iron Age*, Nov. 12, 1891) finds in analyzing samples taken from every other bed of a cast of pig iron that the silicon varies considerably, the iron coming first from the furnace having generally the highest percentage. In one series of tests the silicon decreased from 2.040 to 1.713 from the first bed to the eleventh. In another case the third bed had 1.260 Si., the seventh 1.718, and the eleventh 1.101. He also finds that the silicon varies in each pig, being higher at the point than at the butt. Some of his figures are: point of pig 2.328 Si., butt of same 2.157; point of pig 1.834, butt of same 1.787.

**Some Tests of Cast Iron.** (G. Lanza, *Trans. A. S. M. E.*, x., 187.)—The chemical analyses were as follows:

	Gun Iron, per cent.	Common Iron, per cent.
Total carbon.....	3.51	.....
Graphite.....	2.80	.....
Sulphur.....	0.133	0.173
Phosphorus.....	0.155	0.413
Silicon.....	1.140	1.89

The test specimens were 26 inches long and square in section; those tested with the skin on being very nearly one inch square, and those tested with the skin removed being cast nearly one and one quarter inches square, and afterwards planed down to one inch square.

	Tensile Strength.	Elastic Limit.	Modulus of Elas- ticity.
Unplaned common. 20,200 to 23,000 T. S. Av. =	22,066	6,500	13,194,233
Planed common.... 20,300 to 20,800 " " =	20,520	5,833	11,943,953
Unplaned gun..... 27,000 to 28,775 " " =	28,175	11,000	16,130,300
Planed gun..... .. 29,500 to 31,000 " " =	30,500	8,500	15,932,880

The elastic limit is not clearly defined in cast iron, the elongations increasing faster than the increase of the loads from the beginning of the test. The modulus of elasticity is therefore variable, decreasing as the loads increase. For example, see the results of test of a cast-iron bar on p. 314.

**The Strength of Cast Iron** depends on many other things besides its chemical composition. Among them are the size and shape of the casting, the temperature at which the metal is poured, and the rapidity of cooling. Internal stresses are apt to be induced by rapid cooling, and slow cooling tends to cause segregation of the chemical constituents and opening of the grain of the metal, making it weak. The relation of these variable conditions to the strength of cast iron is a complex one and as yet but imperfectly understood. (See "Cast-iron Columns," p. 250.)

The author recommends that in making experiments on the strength of cast iron, bars of several different sizes, such as  $\frac{1}{2}$ , 1,  $1\frac{1}{2}$ , and 2 in. square (or round), should be taken, and the results compared. Tests of bars of one size only do not furnish a satisfactory criterion of the quality of the iron of which they are made. See Trans. A. I. M. E., xxvi., 1017.

### CHEMISTRY OF FOUNDRY IRONS.

(C. A. Meissner, *Columbia College Q'ly*, 1890; *Iron Age*, 1890.)

Silicon is a very important element in foundry irons. Its tendency when not above  $2\frac{1}{2}\%$  is to cause the carbon to separate out as graphite, giving the casting the desired benefits of graphitic iron. Between  $2\frac{1}{2}\%$  and  $3\frac{1}{2}\%$  silicon is best adapted for iron carrying a fair proportion of low silicon scrap and close iron, for ordinarily no mixture should run below  $1\frac{1}{2}\%$  silicon to get good castings.

From 3% to 5% silicon, as occurs in silvery iron, will carry heavy amounts of scrap. Castings are liable to be brittle, however, if not handled carefully as regards proportion of scrap used.

From  $1\frac{1}{2}\%$  to 2% silicon is best adapted for machine work; will give strong clean castings if not much scrap is used with it.

Below 1% silicon seems suited for drills and castings that have to stand great variations in temperature.

Silicon has the effect of making castings fluid, strong, and open-grained; also sound, by its tendency to separate the graphite from the total carbon, and consequent slight expansion of the iron on cooling, causing it to fill out thoroughly. Phosphorus, when high, has a tendency to make iron fluid, retain its heat longer, thereby helping to fill out all small spaces in casting. It makes iron brittle, however, when above  $\frac{3}{4}\%$  in castings. It is excellent when high to use in a mixture of low-phosphorus irons, up to  $1\frac{1}{2}\%$  giving good results, but, as said before, the casting should be below  $\frac{3}{4}\%$ . It has a strong tendency when above 1% in pig to make the iron less graphitic, preventing the separation of graphite.

Sulphur in open iron seldom bothers the founder, as it is seldom present to any extent. The conditions causing open iron in the furnace cause low sulphur. A little manganese is an excellent antidote against sulphur in the furnace. Irons above 1% manganese seldom have any sulphur of any consequence.

Graphite is the all-important factor in foundry irons; unless this is present in sufficient amount in the casting, the latter will be liable to be poor. Graphite causes iron to slightly expand on cooling, makes it soft, tough and fluid. (The statement as to expansion on cooling is denied by W. J. Keep.)

**Relation of the Appearance of Fracture to the Chemical Composition.**—S. H. Chauvenet says when run [from the blast-furnace] the lower bed is almost always close grain, but shows practically the same analysis as the large grain in the rest of the cast. If the iron runs rapidly, the lower bed may have as large grain as any in the cast. If the iron runs rapidly, for, say six beds and some obstruction in the tap-hole causes the seventh bed to fill up slowly and sluggishly, this bed may be close-grain, although the eighth bed, if the obstruction is removed will be open-grain. Neither the graphitic carbon nor the silicon seems to have any influence on the fracture in these cases, since by analysis the graphite and silicon is the same in each. The question naturally arises whether it would not be better to be guided by the analysis than by the fracture. The fracture is a guide, but it is not an infallible guide. Should not the open- and the close-grain iron of the same cast be numbered under the same grade when they have the same analysis?

Mr. Meissner had many analyses made for the comparison of fracture

with analysis, and unless the condition of furnace, whether the iron ran fast or slow, and from what part of pig bed the sample is taken, are known, the fracture is often very misleading. Take the following analyses :

	A.	B.	C.	D.	E.	F.
Silicon.....	4.315	4.818	4.270	3.328	3.869	3.861
Sulphur.....	0.008	0.008	0.007	0.033	0.006	0.006
Graphitic car..	3.010	2.757	2.680	2.243	3.070	3.100
Comb. carbon.....	.....	.....	.....	.....	0.108	0.096

- A. Very close-grain iron, dark color, by fracture, gray forge.
  - B. Open-grain, dark color, by fracture, No. 1.
  - C. Very close-grain, by fracture, gray forge.
  - D. Medium-grain, by fracture, No. 2, but much brighter and more open than A, C, or F.
  - E. Very large, open-grain, dark color, by fracture, No. 1.
  - F. Very close-grain, by fracture, gray forge.
- By comparing analyses A and B, or E and F, it appears that the close-grain iron is in each case the highest in graphitic carbon. Comparing A and E, the graphite is about the same, but the close-grain is highest in silicon.

**Analyses of Foundry Irons.** (C. A. Meissner.)

DESCRIPTION OF SAMPLES.—No. 1. Well known Ohio Scotch iron, almost silvery, but carries two-thirds scrap ; made from part black-band ore. Very successful brand. The high silicon gives it its scrap-carrying capacity.

No. 2. Brier Hill Scotch castings, made at scale works ; castings demanding more fluidity than strength.

No. 3. Formerly a famous Ohio Scotch brand, not now in the market Made mainly from black-band ore.

No. 4. A good Ohio Scotch, very soft and fluid; made from black-band ore-mixture.

Nos. 5a and 5b. Brier Hill Scotch iron and casting; made for stove purposes; 350 lbs. of iron used to 150 lbs. scrap gave very soft fluid iron; worked well.

No. 6a. Shows comparison between Summerlee (Scotch) (6a) and Brier Hill Scotch (6b). Drillings came from a Cleveland foundry, which found both irons closely alike in physical and working quality.

No. 7. One of the best southern brands, very hard to compete with, owing to its general qualities and great regularity of grade and general working.

18	0.80	0.164	0.90	0.015	.....	.....	1

DESCRIPTION OF SAMPLES.—No. 8. A famous Southern brand noted for fine machine castings.

No. 9. Also a Southern brand, a very good machine iron.

Nos. 10a and 10b. Formerly one of the best known Ohio brands. Does not shrink; is very fluid and strong. Foundries having used this have reported very favorably on it.

No. 11. Iron from Brier Hill Co., made to imitate No. 3; was stronger than No. 3; did not pull castings; was fluid and soft.

No. 12. Copy of a very strong English machine iron.

No. 13. A Pennsylvania iron, very tough and soft. This is partially Bessemer iron, which accounts for strength, while high silicon makes it soft.

No. 14. Castings made from Brier Hill Co.'s machine brand for scale works, very satisfactory, strong, soft and fluid.

No. 15. Castings made from Brier Hill Co.'s one half machine brand, one half Scotch brand, for scale works, castings desired to be of fair strength, but very fluid and soft.

No. 16a. Brier Hill machine brand made to compete with No. 3.

No. 16b. Castings (clothes-hooks) from same, said to have worked badly, castings being white and irregular. Analysis proved that some other iron too high in manganese had been used, and probably not well mixed.

No. 17. A Pennsylvania iron, no shrinkage, excellent machine iron, soft and strong.

No. 18. A very good quality Northern charcoal iron.

#### “Standard Grades” of the Brier Hill Iron and Coal Company.

*Brier Hill Scotch Iron.—Standard Analysis, Grade Nos. 1 and 2.*

Silicon .....	2.00 to 3.00
Phosphorus.....	0.50 to 0.75
Manganese.....	2.00 to 2.50

Used successfully for scales, mowing-machines, agricultural implements, novelty hardware, sounding-boards, stoves, and heavy work requiring no special strength.

*Brier Hill Silvery Iron.—Standard Analysis, Grade No. 1.*

Silicon .....	3.50 to 5.50
Phosphorus.....	1.00 to 1.50
Manganese .....	2.00 to 2.25

Used successfully for hollow-ware, car-wheels, etc., stoves, bumpers, and similar work, with heavy amounts of scrap in all cases. Should be mainly used where fluidity and no great strength is required, especially for heavy work. When used with scrap or close pig low in phosphorus, castings of considerable strength and great fluidity can be made

*Fairly Heavy Machine Iron.—Standard Analysis, Grade No. 1.*

Silicon .....	1.75 to 2.50
Phosphorus...	0.50 to 0.60
Manganese.....	1.20 to 1.40

The best iron for machinery, wagon-boxes, agricultural implements, pump-works, hardware specialties, lathes, stoves, etc., where no large amounts of scrap are to be carried, and where strength, combined with great fluidity and softness, are desired. Should not have much scrap with it.

*Regular Machine Iron.—Standard Analysis, Grade Nos. 1 and 2.*

Silicon.....	1.50 to 2.00
Phosphorus.....	0.30 to 0.50
Manganese.....	0.80 to 1.00

Used for hardware, lawn-mowers, mower and reaper works, oil-well machinery, drills, fine machinery, stoves, etc. Excellent for all small fine castings requiring fair fluidity, softness, and mainly strength. Cannot be well used alone for large castings, but gives good results on same when used with above-mentioned heavy machine grade; also when used with the Scotch in right proportion. Will carry but little scrap, and should be used alone for good strong castings.

*For Axles and Materials Requiring Great Strength, Grade No. 2.*

Silicon.....	1.50
Phosphorus.....	0.200 and less.
Manganese .....	0.80

This gave excellent results.

A good neutral iron for guns, etc., will run about as follows :

Silicon.....	1.00
Phosphorus.....	0.25
Sulphur.....	0.20
Manganese.....	none.

It should be open No. 1 iron.

This gives a very tough, elastic metal. More sulphur would make tough but decrease elasticity.

For fine castings demanding elegance of design but no strength, phosphorus to 3.00% is good. Can also stand 1.50% to 2.00% manganese. For work of a hard, abrasive character manganese can run 2.00% in casting.

**Analyses of Castings.**

Sample No.	Silicon.	Phos-phorus.	Manganese	Sulphur.	Graphite.	Comb. Carbon.
31	2.50	1.400	2.20	.....	.....	.....
32	0.85	0.351	0.92	0.030	.....	.....
33	1.53	0.327	1.08	0.040	3.10	0.58
34a	1.84	0.577	1.04	.....	.....	.....
34b	2.20	0.742	1.10	.....	.....	.....
34c	2.50	1.208	1.16	.....	.....	.....
35a	2.80	0.418	0.54	.....	.....	.....
35b	3.10	1.280	1.14	.....	.....	.....
35c	3.30	0.879	0.80	.....	.....	.....
35d	2.88	0.408	1.10	.....	.....	.....
35e	4.50	0.660	0.78	.....	.....	.....
36	3.43	1.439	0.90	0.025	.....	.....
37a	2.68	0.900	1.30	.....	.....	.....
37b	1.90	0.980	1.20	.....	.....	.....

No. 31. Sewing-machine casting, said to be very fluid and good casting. This is an odd analysis. I should say it would have been too hard and brittle, yet no complaint was made.

No. 32. Very good machine casting, strong, soft, no shrinkage.

No. 33. Drillings from an annealer-box that stood the heat very well.

No. 34a. Drillings from door-hinge, very strong and soft.

No. 34b. Drillings from clothes-hooks, tough and soft, stood severe hammering.

No. 34c. Drillings from window-blind hinge, broke off suddenly at light strain. Too high phosphorus.

No. 35a. Casting for heavy ladle support, very strong.

Nos 35b and 35c. Broke after short usage. Phosphorus too high. Car-bumpers.

No. 35d. Elbow for steam heater, very tough and strong.

No. 36. Cog-wheels, very good, shows absolutely no shrinkage.

No. 37. Heater top network, requiring fluidity but no strength.

No. 37a. Gray part of above.

No. 37b. White, honeycombed part of above. Probably bad mixing and got chilled suddenly.

### STRENGTH OF CAST IRON.

Rankine gives the following figures:

Various qualities, T. S.....	13,400 to	29,000, average	16,500
Compressive strength.....	82,000 to	145,000, "	112,000
Modulus of elasticity.....	14,000,000 to	22,900,000, "	17,000,000

**Specific Gravity and Strength.** (Major Wade, 1856.)

Third-class guns: Sp. Gr. 7.087, T. S. 20,148. Another lot: least Sp. Gr. 7.163, T. S. 22,402.

Second-class guns: Sp. Gr. 7.154, T. S. 24,767. Another lot: mean Sp. Gr. 7.302, T. S. 27,332.

First class guns: Sp. Gr. 7.204, T. S. 28,805. Another lot: greatest Sp. Gr. 7.402, T. S. 31,027.

**Strength of Charcoal Pig Iron.**—Pig iron made from Salisbury ores, in furnaces at Wassaic and Millerton, N. Y., has shown over 40,000 lbs. T. S. per square inch, one sample giving 42,281 lbs. Muirkirk, Md., iron tested at the Washington Navy Yard showed: average for No. 2 iron, 21,601 lbs.; No. 3, 23,959 lbs.; No. 4, 41,329 lbs.; average density of No. 4, 7.336 (J. C. I. W., v. p. 44.)

Nos. 3 and 4 charcoal pig iron from Chapinville, Conn., showed a tensile strength per square inch of from 34,761 lbs. to 41,882 lbs. Charcoal pig iron from Shelby, Ala. (tests made in August, 1891), showed a strength of 34,800 lbs. for No. 3; No. 4, 39,675 lbs.; No. 5, 46,450 lbs.; and a mixture of equal parts of Nos. 2, 3, 4, and 5, 41,470 lbs. (*Bull. I. & S. A.*)

**Variation of Density and Tenacity of Gun-irons.**—An increase of density invariably follows the rapid cooling of cast iron, and as a general rule the tenacity is increased by the same means. The tenacity generally increases quite uniformly with the density, until the latter ascends to some given point; after which an increased density is accompanied by a diminished tenacity.

The turning-point of density at which the best qualities of gun-iron attain their maximum tenacity appears to be about 7.30. At this point of density, or near it, whether in proof-bars or gun-heads, the tenacity is greatest.

As the density of iron is increased its liquidity when melted is diminished. This causes it to congeal quickly, and to form cavities in the interior of the casting. (Pamphlet of Builders' Iron Foundry, 1893.)

**Specifications for Cast Iron for the World's Fair Buildings, 1892.**—Except where chilled iron is specified, all castings shall be of tough gray iron, free from injurious cold-shuts or blow-holes, true to pattern, and of a workmanlike finish. Sample pieces 1 in. square, cast from the same heat of metal in sand moulds, shall be capable of sustaining on a clear span of 4 feet 6 inches a central load of 500 lbs. when tested in the rough bar.

**Specifications for Tests of Cast Iron in 12" B. L. Mortars.** (Pamphlet of Builders Iron Foundry, 1893.)—*Charcoal Gun Iron.*—The tensile strength of the metal must average at each end at least 30,000 lbs. per square inch; no specimen to be over 37,000 lbs. per square inch; but one specimen from each end may be as low as 28,000 lbs. per square inch. The

long extension specimens will not be considered in making up these averages, but must show a good elongation and an ultimate strength, for each specimen, of not less than 24,000 lbs. The density of the metal must be such as to indicate that the metal has been sufficiently refined, but not carried so high as to impair the other qualities.

**Specifications for Grading Pig Iron for Car Wheels by Chill Tests made at the Furnace.** (Penna. R. R. Specifications, 1883.)—The chill cup is to be filled, *even full*, at about the middle of every cast from the furnace. The test-piece so made will be 7½ inches long, 3½ inches wide, and 1¾ inches thick, and is to be broken across the centre when entirely cold. The depth of chill will be shown on the bottom of the test-piece, and is to be measured by the clean white portion to the point where gray specks begin to show in the white. The grades are to be by eighths of an inch, viz., ⅛, ¼, ⅜, ½, ⅝, ¾, ⅞, etc., until the iron is mottled; the lowest grade being ⅛ of an inch in depth of chill. The pigs of each cast are to be marked with the depth of chill shown by its test-piece, and each grade is to be kept by itself at the furnace and in forwarding.

**Mixture of Cast Iron with Steel.**—Car wheels are sometimes made from a mixture of charcoal iron, anthracite iron, and Bessemer steel. The following shows the tensile strength of a number of tests of wheel mixtures, the average tensile strength of the charcoal iron used being 22,000 lbs.:

	lbs. per sq. in.
Charcoal iron with 2½% steel.....	22,467
“ “ “ 3¾% steel.....	26,733
“ “ “ 6¼% steel and 6¼% anthracite.....	24,400
“ “ “ 7⅓% steel and 7½% anthracite ..	28,150
“ “ “ 2½% steel, 2½% wro't iron, and 6¼% anth...	25,550
“ “ “ 5 % steel, 5% wro't iron, and 10% anth....	26,500

(*Jour. C. I. W.*, iii. p. 184.)

**Cast Iron Partially Bessemerized.**—Car wheels made of partially Bessemerized iron (blown in a Bessemer converter for 3½ minutes), chilled in a chill test mould over an inch deep, just as a test of cold blast charcoal iron for car wheels would chill. Car wheels made of this blown iron have run 250,000 miles. (*Jour. C. I. W.*, vi. p. 77.)

**Bad Cast Iron.**—On October 15, 1891, the cast-iron fly-wheel of a large pair of Corliss engines belonging to the Amoskeag Mfg. Co., of Manchester, N. H., exploded from centrifugal force. The fly-wheel was 30 feet diameter and 110 inches face, with one set of 12 arms, and weighed 116,000 lbs. After the accident, the rim castings, as well as the ends of the arms, were found to be full of flaws, caused chiefly by the drawing and shrinking of the metal. Specimens of the metal were tested for tensile strength, and varied from 15,000 lbs. per square inch in sound pieces to 1000 lbs. in spongy ones. None of these flaws showed on the surface, and a rigid examination of the parts before they were erected failed to give any cause to suspect their true nature. Experiments were carried on for some time after the accident in the Amoskeag Company's foundry in attempting to duplicate the flaws, but with no success in approaching the badness of these castings.

**MALLEABLE CAST IRON.**

Malleableized cast iron, or malleable iron castings, are castings made of ordinary cast iron which have been subjected to a process of decarbonization, which results in the production of a crude wrought iron. Handles, latches, and other similar articles, cheap harness mountings, plowshares, iron handles for tools, wheels, and pinions, and many small parts of machinery, are made of malleable cast iron. For such pieces charcoal cast iron of the best quality (or other iron of similar chemical composition), should be selected. Coke irons low in silicon and sulphur have been used in place of charcoal irons. The castings are made in the usual way, and are then imbedded in oxide of iron, in the form, usually, of hematite ore, or in peroxide of manganese, and exposed to a full red-heat for a sufficient length of time, to insure the nearly complete removal of the carbon. This decarbonization is conducted in cast-iron boxes, in which the articles, if small, are packed in alternate layers with the decarbonizing material. The largest pieces require the longest time. The fire is quickly raised to the maximum temperature, but at the close of the process the furnace is cooled very slowly. The operation requires from three to five days with ordinary small castings, and may take two weeks for large pieces.

**Rules for Use of Malleable Castings,** by Committee of Master Carbuilders' Ass'n, 1890.

1. Never run abruptly from a heavy to a light section.
2. As the strength of malleable cast iron lies in the skin, expose as much surface as possible. A star-shaped section is the strongest possible from which a casting can be made. For brackets use a number of thin ribs instead of one thick one.
3. Avoid all round sections; practice has demonstrated this to be the weakest form. Avoid sharp angles.
4. Shrinkage generally in castings will be  $\frac{3}{16}$  in. per foot.

**Strength of Malleable Cast Iron.**—Experiments on the strength of malleable cast iron, made in 1891 by a committee of the Master Carbuilders' Association. The strength of this metal varies with the thickness, as the following results on specimens from  $\frac{1}{4}$  in. to  $1\frac{1}{2}$  in. in thickness show:

Dimensions.		Tensile Strength.	Elongation.	Elastic Limit.
in.	in.	lb. per sq. in.	per cent in 4 in.	lb. per sq. in.
1.52	by .25	31,700	2	21,100
1.52	“ .39	33,700	2	15,200
1.53	“ .5	32,800	2	17,000
1.53	“ .64	32,100	2	19,400
2.	“ .78	25,100	$1\frac{1}{2}$	15,400
1.54	“ .88	33,600	$1\frac{1}{2}$	19,300
1.06	“ 1.02	30,600	1	17,600
1.28	“ 1.3	27,400	1	
1.52	“ 1.54	28,200	$1\frac{1}{2}$	

The low ductility of the metal is worthy of notice. The committee gives the following table of the comparative tensile resistance and ductility of malleable cast iron, as compared with other materials:

	Ultimate Strength, lb. per sq. in.	Comparative Strength; Cast Iron = 1.	Elongation Per Cent in 4 in.	Comparative Ductility; Malleable Cast Iron = 1.
Cast iron .....	20,000	1	0.35	0.17
Malleable cast iron.	32,000	1.6	2.00	1
Wrought iron .....	50,000	2.5	20.00	10
Steel castings .....	60,000	3	10.00	5

Another series of tests, reported to the Association in 1892, gave the following:

Thick-ness.	Width.	Area.	Elastic Limit.	Ultimate Strength.	Elongation in 8 in.
in.	in.	sq in.	lb. per sq.	lb. per sq. in.	per cent.
.271	2.81	.7615	23,520	32,620	1.5
.293	2.78	.8145	22,650	28,160	.6
.39	2.82	1.698	20,595	32,060	1.5
.41	2.79	1.144	20,230	28,850	1.0
.529	2.76	1.46	19,520	27,875	1.1
.661	2.81	1.857	18,840	25,700	.7
.8	2.76	2.508	18,390	25,120	1.1
1.025	2.82	2.890	18,220	28,720	1.5
1.117	2.81	3.133	17,050	25,510	1.3
1.021	2.82	2.879	18,410	26,950	1.3

WROUGHT IRON.

**Influence of Chemical Composition on the Properties of Wrought Iron.** (Beardslee on Wrought Iron and Chain Cables. Abridgement by W. Kent. Wiley & Sons, 1879.)—A series of 2000 tests of specimens from 14 brands of wrought iron, most of them of high repute, was made in 1877 by Capt. L. A. Beardslee, U.S.N., of the United States Testing Board. Forty-two chemical analyses were made of these irons, with a view to determine what influence the chemical composition had upon the strength, ductility, and welding power. From the report of these tests by A. L. Holley the following figures are taken :

Brand.	Average Tensile Strength.	Chemical Composition.					
		S.	P.	Si.	C.	Mn.	Slag.
L	66,598	trace	{ 0.065 0.084	0.080 0.105	0.212 0.512	0.005 0.029	0.192 0.452
P	54,363	{ 0.009 0.001	0.250 0.095	0.182 0.028	0.033 0.066	0.033 0.009	0.848 1.214
B	52,764	0.008	0.231	0.156	0.015	0.017	.....
J	51,754	{ 0.003 0.005	0.140 0.291	0.182 0.321	0.027 0.051	trace 0.053	0.678 1.724
O	51,134	{ 0.004 0.005	0.067 0.078	0.065 0.073	0.045 0.042	0.007 0.005	1.168 0.974
C	50,765	0.007	0.169	0.154	0.042	0.021	.....

Where two analyses are given they are the extremes of two or more analyses of the brand. Where one is given it is the only analysis. Brand L should be classed as a puddled steel.

ORDER OF QUALITIES GRADED FROM No. 1 TO No. 19.

Brand.	Tensile Strength.	Reduction of Area.	Elongation.	Welding Power.
L	1	18	19	most imperfect.
P	6	6	3	badly.
B	12	16	15	best.
J	16	19	18	rather badly.
O	18	1	4	very good.
C	19	12	16	—

The reduction of area varied from 54.2 to 25.9 per cent, and the elongation from 29.9 to 8.3 per cent.

Brand O, the purest iron of the series, ranked No. 18 in tensile strength, but was one of the most ductile; brand B, quite impure, was below the average both in strength and ductility, but was the best in welding power; P, also quite impure, was one of the best in every respect except welding, while L, the highest in strength, was not the most pure, it had the least ductility, and its welding power was most imperfect. The evidence of the influence of chemical composition upon quality, therefore, is quite contradictory and confusing. The irons differing remarkably in their mechanical properties, it was found that a much more marked influence upon their qualities was caused by different treatment in rolling than by differences in composition.

In regard to slag Mr. Holley says : "It appears that the smallest and most worked iron often has the most slag. It is hence reasonable to conclude that an iron may be dirty and yet thoroughly condensed."

In his summary of "What is learned from chemical analysis," he says : "So far, it may appear that little of use to the makers or users of wrought iron has been learned. . . . The character of steel can be surely predicated on the analyses of the materials; that of wrought iron is altered by subtle and unobserved causes."

**Influence of Reduction in Rolling from Pile to Bar on the Strength of Wrought Iron.**—The tensile strength of the irons used in Beardslee's tests ranged from 46,000 to 62,700 lbs. per sq. in., brand L, which was really a steel, not being considered. Some specimens of L gave figures as high as 70,000 lbs. The amount of reduction of sectional

area in rolling the bars has a notable influence on the strength and elastic limit; the greater the reduction from pile to bar the higher the strength.

The following are a few figures from tests of one of the brands:

Size of bar, in. diam.	4	3	2	1	$\frac{1}{2}$	$\frac{1}{4}$
Area of pile, sq. in.:	80	80	72	25	$\frac{9}{9}$	$\frac{3}{3}$
Bar per cent of pile:	15.7	8.83	4.36	3.14	2.17	1.6
Tensile strength, lb.:	46,322	47,761	48,280	51,128	52,275	59,585
Elastic limit, lb.:	23,430	26,400	31,892	36,467	39,126	—

**Specifications for Wrought Iron** (F. H. Lewis, Engineers' Club of Philadelphia, 1891).—1. All wrought iron must be tough, ductile, fibrous, and of uniform quality for each class, straight, smooth, free from cinder-pockets, flaws, buckles, blisters, and injurious cracks along the edges, and must have a workmanlike finish. No specific process or provision of manufacture will be demanded, provided the material fulfils the requirements of these specifications.

2. The tensile strength, limit of elasticity, and ductility shall be determined from a standard test-piece not less than  $\frac{1}{4}$  inch thick, cut from the full-sized bar, and planed or turned parallel. The area of cross-section shall not be less than  $\frac{1}{2}$  square inch. The elongation shall be measured after breaking on an original length of 8 inches.

3. The tests shall show not less than the following results:

For bar iron in tension.....	T. S. = 50,000; E. L. = 26,000; E. L. in 8 in.,	18%
For shape iron in tension...	" = 48,000; " = 26,000; "	15%
For plates under 36 in. wide	" = 48,000; " = 26,000; "	12%
For plates over 36 in. wide..	" = 46,000; " = 25,000; "	10%

4. When full-sized tension members are tested to prove the strength of their connections, a reduction in their ultimate strength of (500 × width of bar) pounds per square inch will be allowed.

5. All iron shall bend, cold, 180 degrees around a curve whose diameter is twice the thickness of piece for bar iron, and three times the thickness for plates and shapes.

6. Iron which is to be worked hot in the manufacture must be capable of bending sharply to a right angle at a working heat without sign of fracture.

7. Specimens of tensile iron upon being nicked on one side and bent shall show a fracture nearly all fibrous.

8. All rivet iron must be tough and soft, and be capable of bending cold until the sides are in close contact without sign of fracture on the convex side of the curve.

**Penna. R. R. Co.'s Specifications for Merchant-bar Iron (1902).**—One bar will be selected for test from each 100 bars in a pile.

All the iron of one size in the shipment will be rejected if the average tensile strength of the specimens representing it falls below 47,000 lbs. or exceeds 53,000 lbs. per sq. in., or if any single specimens show less than 45,000 lbs. per sq. in.

In the case of flat bars which have to be reduced in width for test an allowance of 1,000 lbs. per sq. in. will be made, making the rejection limit 46,000 lbs. per sq. in. All the iron of one size in the shipment will be rejected if the average elongation in 8 ins. falls below the following limits: Rounds,  $\frac{1}{2}$  in. and over, 20%; less than  $\frac{1}{2}$  in., 16%. Flats pulled as rolled, 20%; flats reduced, 16%.

**Nicking and Bending Tests**—When necessary to make nicking and bending tests the iron will be held firmly in a vise, nicked lightly on one side and then broken by a succession of light blows on the nicked side. It must when thus broken show a generally fibrous structure, not more than 25% crystalline, and must be free from admixture of steel.

**Stay-bolt Iron.** (Penna. R. R. Co.'s specifications, 1900.)—Sample bars must show a tensile strength of not less than 48,000 lbs. per sq. in. and an elongation of not less than 25% in 8 ins. One piece from each lot will be threaded in dies with a sharp V thread, 12 to 1 in. and firmly screwed through two holders having a clear space between them of 5 ins. One holder will be rigidly secured to the bed of a suitable machine and the other vibrated at right angles to the axis over a space of  $\frac{1}{4}$  in. or  $\frac{1}{8}$  in. each side of the centre line. Acceptable iron should stand 2,200 double vibrations before breakage.

**Specifications for Wrought Iron for the World's Fair Buildings.** (*Eng'g News*, March 26, 1892.)—All iron to be used in the tensile members of open trusses, laterals, pins and bolts, except plate iron over 8 inches wide, and shaped iron, must show by the standard test-pieces a tensile strength in lbs. per square inch of :

$$52,000 - \frac{7,000 \times \text{area of original bar in sq. in.}}{\text{circumference of original bar in inches}}$$

with an elastic limit not less than half the strength given by this formula, and an elongation of 20% in 8 in.

Plate iron 24 inches wide and under, and more than 8 inches wide, must show by the standard test-pieces a tensile strength of 48,000 lbs. per sq. in. with an elastic limit not less than 26,000 lbs. per square inch, and an elongation of not less than 12%. All plates over 24 inches in width must have a tensile strength not less than 46,000 lbs. with an elastic limit not less than 26,000 lbs. per square inch. Plates from 24 inches to 36 inches in width must have an elongation of not less than 10%; those from 36 inches to 48 inches in width, 8%; over 48 inches in width, 5%.

All shaped iron, flanges of beams and channels, and other iron not herein-before specified, must show by the standard test-pieces a tensile strength in lbs. per square inch of :

$$50,000 - \frac{7,000 \times \text{area of original bar}}{\text{circumference of original bar}}$$

with an elastic limit of not less than half the strength given by this formula, and an elongation of 15% for bars  $\frac{5}{8}$  inch and less in thickness, and of 12% for bars of greater thickness. For webs of beams and channels, specifications for plates will apply.

All rivet iron must be tough and soft, and pieces of the full diameter of the rivet must be capable of bending cold, until the sides are in close contact, without sign of fracture on the convex side of the curve.

**Stay-bolt Iron.**—Mr. Vauclain, of the Baldwin Locomotive Works, at a meeting of the American Railway Master Mechanics' Association, in 1892, says: Many advocate the softest iron in the market as the best for stay-bolts. He believed in an iron as hard as was consistent with heading the bolt nicely. The higher the tensile strength of the iron, the more vibrations it will stand, for it is not so easily strained beyond the yield-point. The Baldwin specifications for stay-bolt iron call for a tensile strength of 50,000 to 52,000 lbs. per square inch, the upper figure being preferred, and the lower being insisted upon as the minimum.

**FORMULÆ FOR UNIT STRAINS FOR IRON AND STEEL IN STRUCTURES.**

(F. H. Lewis, Engineers' Club of Philadelphia, 1891.)

The following formulæ for unit strains per square inch of net sectional area shall be used in determining the allowable working stress in each member of the structure. (For definitions of soft and medium steel see Specifications for Steel.)

**Tension Members.**

	Wrought Iron.	Soft Steel.	Medium Steel.
Floor-beam hangers or suspenders, forged bars . . . . .	Will not be used	Will not be used	7000
Counter-ties . . . . .	6000	" " "	7000
Suspenders, hangers and counters, riveted members, net section . . . . .	5000	5500	7000
Solid rolled beams . . . . .	8000	8000	Will not be used
Riveted truss members and tension flanges of girders, net section . . . . .	$7000 \left(1 + \frac{\text{min.}}{\text{max.}}\right)$	8% greater than iron	$9000 \left(1 + \frac{\text{min.}}{\text{max.}}\right)$
Forged eyebars . . . . .	Will not be used	Will not be used	$9000 \left(1 + \frac{\text{min.}}{\text{max.}}\right)$
Lateral or cross-section rods . . . . .	15,000	16,000	(For eyebars only, 17,000)

**Shearing.**

	Wrought Iron.	Soft Steel.	Medium Steel.
On pins and shop rivets	6000	6600	7200
On field rivets.....	4800	5200	Will not be used
In webs of girders.....	Will not be used	5000	6000

**Bearing.**

	Wrought Iron.	Soft Steel.	Medium Steel.
On projected semi-intrados of main-pin holes .....	12,000	13,200	14,500
On projected semi-intrados of rivet-holes*	12,000	13,200	14,500
On lateral pins....	15,000	16,500	18,000
Of bed-plates on masonry ... ..	250 lbs. per sq. in.		

\* Excepting that in pin-connected members taking alternate stresses, the bearing stress must not exceed 9000 lbs. for iron or steel.

**Bending.**

On extreme fibres of pins when centres of bearings are considered as points of application of strains:

Wrought Iron, 15,000.      Soft Steel, 16,000.      Medium Steel, 17,000.

**Compression Members.**

	Wrought Iron.	Soft Steel.	Medium Steel.
Chord sections :			
Flat ends.....	$7000 \left( 1 + \frac{\text{min.}}{\text{max.}} \right) - 30 \frac{l}{r}$	} 10% greater than iron	} 20% greater than iron
One flat and one pin end..	$7000 \left( 1 + \frac{\text{min.}}{\text{max.}} \right) - 35 \frac{l}{r}$		
Chords with pin ends and all end-posts .....	$7000 \left( 1 + \frac{\text{min.}}{\text{max.}} \right) - 40 \frac{l}{r}$		
All trestle-posts.....	$7000 \left( 1 + \frac{\text{min.}}{\text{max.}} \right) - 35 \frac{l}{r}$		
Intermediate posts.....	$7500 - 40 \frac{l}{r}$		
Lateral struts, and compression in collision struts, stiff suspenders and stiff chords.....	$10,500 - 50 \frac{l}{r}$		

In which formulæ  $l$  = length of compression member in inches, and  $r$  = least radius of gyration of member in inches. No compression member shall have a length exceeding 45 times its least width, and no post should be used in which  $l \div r$  exceeds 125.

**Members Subject to Alternate Tension and Compression.**

	Wrought Iron.	Soft Steel.	Medium Steel.
For compression only...	Use the formulæ above		
For the greatest stress..	$7000 \left( 1 - \frac{\text{max. lesser}}{2 \text{ max. greater}} \right)$	8% greater than iron	20% greater than iron

Use the formula giving the greatest area of section.

The compression flanges of beams and plate girders shall have the same cross-section as the tension flanges.

W. H. Burr, discussing the formulæ proposed by Mr. Lewis, says: "Taking the results of experiments as a whole, I am constrained to believe that they indicate at least 15% increase of resistance for soft-steel columns over those of wrought iron, with from 20% to 25% for medium steel, rather than 10% and 20% respectively.

"The high capacity of soft steel for enduring torture fits it eminently for alternate and combined stresses, and for that reason I would give it 15% increase over iron, with about 22% for medium steel.

"Shearing tests on steel seem to show that 15% and 22% increases, for the two grades respectively, are amply justified.

"I should not hesitate to assign 15% and 22% increases over values for iron for bearing and bending of soft and medium steel as being within the safe limits of experience. Provision should also be made for increasing pin-shearing, bending and bearing stresses for increasing ratios of fixed to moving loads."

**Maximum Permissible Stresses in Structural Materials used in Buildings.** (Building Ordinances of the City of Chicago, 1893.) Cast iron, crushing stress: For plates, 15,000 lbs. per square inch; for lintels, brackets, or corbels, compression 13,500 lbs. per square inch, and tension 3000 lbs. per square inch. For girders, beams, corbels, brackets, and trusses, 16,000 lbs. per square inch for steel and 12,000 lbs. for iron.

For plate girders :

$$\text{Flange area} = \frac{\text{maximum bending moment in ft.-lbs.}}{CD.}$$

$D$  = distance between centre of gravity of flanges in feet.

$C$  =  $\begin{cases} 13,500 \text{ for steel.} \\ 10,000 \text{ for iron.} \end{cases}$

$$\text{Web area} = \frac{\text{maximum shear}}{C}. \quad C = \begin{cases} 10,000 \text{ for steel,} \\ 6,000 \text{ for iron.} \end{cases}$$

For rivets in single shear per square inch of rivet area :

	Steel.	Iron.
If shop-driven.....	9000 lbs.	7500 lbs.
If field-driven .....	7500 "	6000 "

For timber girders :

$$S = \frac{cbd^2}{l}.$$

$b$  = breadth of beam in inches.  
 $d$  = depth of beam in inches.  
 $l$  = length of beam in feet.  
 $c$  =  $\begin{cases} 160 \text{ for long-leaf yellow pine,} \\ 120 \text{ for oak,} \\ 100 \text{ for white or Norway pine.} \end{cases}$

**Proportioning of Materials in the Memphis Bridge** (Geo. S. Morison, *Trans. A. S. C. E.*, 1893).—The entire superstructure of the Memphis bridge is of steel and it was all worked as steel, the rivet-holes being drilled in all principal members and punched and reamed in the lighter members.

The tension members were proportioned on the basis of allowing the dead load to produce a strain of 20,000 lbs. per square inch, and the live load a strain of 10,000 lbs. per square inch. In the case of the central span, where the dead load was twice the live load, this corresponded to 15,000 lbs. total strain per square inch, this being the greatest tensile strain.

The compression members were proportioned on a somewhat arbitrary basis. No distinction was made between live and dead loads. A maximum strain of 14,000 lbs. per square inch was allowed on the chords and other large compression members where the length did not exceed 16 times the least transverse dimension, this strain being reduced 750 lbs. for each additional unit of length. In long compression members the maximum length was limited to 30 times the least transverse dimension, and the strains limited to 6,000 lbs. per square inch, this amount being increased by 200 lbs. for each unit by which the length is decreased.

Wherever reversals of strains occur the member was proportioned to resist the sum of compression and tension on whichever basis (tension or compression) there would be the greatest strain per square inch; and, in addition, the net section was proportioned to resist the maximum tension, and the gross section to resist the maximum compression.

The floor beams and girders were calculated on the strain being limited to 10,000 lbs. per square inch in extreme fibres. Rivet-holes in cover-plates and flanges were deducted.

The rivets of steel in drilled or reamed holes were proportioned on the basis of a bearing strain of 15,000 lbs. per square inch and a shearing strain of 7500 lbs. per square inch, and special pains were taken to get the double shear in as many rivets as possible. This was the requirement for shop rivets. In the case of field rivets, the number was increased one-half.

The pins were proportioned on the basis of a bearing strain of 18,000 lbs. per square inch and a bending strain of 20,000 lbs. per square inch in extreme fibre, the diameters of the pins being never made more than one inch less than the width of the largest eye-bar attaching to them.

The weight on the rollers of the expansion joint on Pier II is 40,000 lbs. per linear foot of roller, or 3,333 lbs. per linear inch, the rollers being 15 ins. in diameter.

As the sections of the superstructure were unusually heavy, and the strains from dead load greatly in excess of those from moving load, it was thought best to use a slightly higher steel than is now generally used for lighter structures, and to work this steel without punching, all holes being drilled. A somewhat softer steel was used in the floor-system and other lighter parts.

The principal requirements which were to be obtained as the results of tests on samples cut from finished material were as follows:

	Max. Ultimate Strength, lbs. per sq. inch.	Min. Ultimate Strength, lbs. per sq. inch.	Min. Elastic Limit, lbs. per sq. in.	Min. percentage of Elongation in 8 inches.	Min. Percentage of Reduction at Fracture
High-grade steel.	78,500	69,000	40,000	18	38
Eye-bar steel....	75,000	66,000	38,000	20	40
Medium steel....	72,500	64,000	37,000	22	44
Soft steel.....	63,000	55,000	30,000	28	50

### TENACITY OF METALS AT VARIOUS TEMPERATURES.

The British Admiralty made a series of experiments to ascertain what loss of strength and ductility takes place in gun-metal compositions when raised to high temperatures. It was found that all the varieties of gun-metal suffer a gradual but not serious loss of strength and ductility up to a certain temperature, at which, within a few degrees, a great change takes place, the strength falls to about one half the original, and the ductility is wholly gone. At temperatures above this point, up to 500, there is little, if any, further loss of strength; the temperature at which this great change and loss of strength takes place, although uniform in the specimens cast from the same pot, varies about 100° in the same composition cast at different temperatures, or with some varying conditions in the foundry process. The temperature at which the change took place in No. 1 series was ascertained to be about 370°, and in that of No. 2, at a little over 250°. Whatever may be the cause of this important difference in the same composition, the fact stated may be taken as certain. Rolled Muntz metal and copper are satisfactory up to 500°, and may be used as securing-bolts with safety. Wrought iron, Yorkshire and remanufactured, increase in strength up to 500°, but lose slightly in ductility up to 300°, where an increase begins and continues up to 500°, where it is still less than at the ordinary temperature of the atmosphere. The strength of Landore steel is not affected by temperature up to 500°, but its ductility is reduced more than one half. (*Iron*, Oct. 6, 1877.)

**Tensile Strength of Iron and Steel at High Temperatures.**—James E. Howard's tests (*Iron Age*, April 10, 1890) show that the tensile strength of steel diminishes as the temperature increases from 0° until a minimum is reached between 200° and 300° F., the total decrease being about 4000 lbs. per square inch in the softer steels, and from 6000 to 8000 lbs. in steels of over 80,000 lbs. tensile strength. From this minimum point the strength increases up to a temperature of 400° to 650° F., the maximum being reached earlier in the harder steels, the increase amounting to from 10,000 to 20,000 lbs. per square inch above the minimum strength at from 200°

to 300°. From this maximum, the strength of all the steel decreases steadily at a rate approximating 10,000 lbs. decrease per 100° increase of temperature. A strength of 20,000 lbs. per square inch is still shown by .10 C. steel at about 1000° F., and by .60 to 1.00 C. steel at about 1600° F.

The strength of wrought iron increases with temperature from 0° up to a maximum at from 400 to 600° F., the increase being from 8000 to 10,000 lbs. per square inch, and then decreases steadily till a strength of only 6000 lbs. per square inch is shown at 1500° F.

Cast iron appears to maintain its strength, with a tendency to increase, until 900° is reached, beyond which temperature the strength gradually diminishes. Under the highest temperatures, 1500° to 1600° F., numerous cracks on the cylindrical surface of the specimen were developed prior to rupture. It is remarkable that cast iron, so much inferior in strength to the steels at atmospheric temperature, under the highest temperatures has nearly the same strength the high-temper steels they have.

**Strength of Iron and Steel Boiler-plate at High Temperatures.** (Chas. Huston, *Jour. F. I.*, 1877.)

**Strength of Wrought Iron and Steel at High Temperatures.** (*Jour. F. I.*, cxii., 1881, p. 241.) Kollmann's experiments at Oberhausen included tests of the tensile strength of iron and steel at temperatures ranging between 70° and 2000° F. Three kinds of metal were tested, viz., fibrous iron having an ultimate tensile strength of 52,464 lbs., an elastic strength of 38,280 lbs., and an elongation of 17.5%; fine-grained iron having for the same elements values of 55,892 lbs., 39,113 lbs., and 20%; and Bessemer steel having values of 84,826 lbs., 55,029 lbs., and 14.5%. The mean ultimate tensile strength of each material expressed in per cent of that at ordinary atmospheric temperature is given in the following table, the fifth column of which exhibits, for purposes of comparison, the results of experiments carried on by a committee of the Franklin Institute in the years 1832-36.

Temperature Degrees F.	Fibrous Wrought Iron, p. c.	Fine-grained Iron, per cent.	Bessemer Steel, per cent.	Franklin Institute, per cent.

**The Effect of Cold on the Strength of Iron and Steel.—**

The following conclusions were arrived at by Mr. Styffe in 1865:  
 (1) That the absolute strength of iron and steel is not diminished by cold, but that even at the lowest temperature which ever occurs in Sweden it is at least as great as at the ordinary temperature (about 60° F.).

(2) That neither in steel nor in iron is the extensibility less in severe cold than at the ordinary temperature.

(3) That the limit of elasticity in both steel and iron lies higher in severe cold.

(4) That the modulus of elasticity in both steel and iron is increased on reduction of temperature, and diminished on elevation of temperature ; but that these variations never exceed 0.05 % for a change of temperature of 1.8° F., and therefore such variations, at least for ordinary purposes, are of no special importance.

Mr. C. P. Sandberg made in 1867 a number of tests of iron rails at various temperatures by means of a falling weight, since he was of opinion that, although Mr. Styffe's conclusions were perfectly correct as regards tensile strength, they might not apply to the resistance of iron to impact at low temperatures. Mr. Sandberg convinced himself that "the breaking strain" of iron, such as was usually employed for rails, "as tested by sudden blows or shocks, is considerably influenced by cold ; such iron exhibiting at 10° F. only from one third to one fourth of the strength which it possesses at 84° F." Mr. J. J. Webster (Inst. C. E., 1880) gives reasons for doubting the accuracy of Mr. Sandberg's deductions, since the tests at the lower temperature were nearly all made with 21-ft. lengths of rail, while those at the higher temperatures were made with short lengths, the supports in every case being the same distance apart.

W. H. Barlow (Proc. Inst. C. E.) made experiments on bars of wrought iron, cast iron, malleable cast iron, Bessemer steel, and tool steel. The bars were tested with tensile and transverse strains, and also by impact ; one half of them at a temperature of 50° F., and the other half at 5° F. The lower temperature was obtained by placing the bars in a freezing mixture, care being taken to keep the bars covered with it during the whole time of the experiments.

The results of the experiments were summarized as follows :

1. When bars of wrought iron or steel were submitted to a tensile strain and broken, their strength was not affected by severe cold (5° F.), but their ductility was increased about 1% in iron and 3% in steel.
2. When bars of cast iron were submitted to a transverse strain at a low temperature, their strength was diminished about 3% and their flexibility about 16%.
3. When bars of wrought iron, malleable cast iron, steel, and ordinary cast iron were subjected to impact at a temperature of 5° F., the force required to break them, and the extent of their flexibility, were reduced as follows, viz.:

	Reduction of Force of Impact, per cent.	Reduction of Flexi- bility, per cent.
Wrought iron, about.....	3	18
Steel (best cast tool), about.....	3½	17
Malleable cast iron, about.....	4½	15
Cast iron, about.....	21	not taken

The experience of railways in Russia, Canada, and other countries where the winter is severe is that the breakages of rails and tires are far more numerous in the cold weather than in the summer. On this account a softer class of steel is employed in Russia for rails than is usual in more temperate climates.

The evidence extant in relation to this matter leaves no doubt that the capability of wrought iron or steel to resist impact is reduced by cold. On the other hand, its static strength is not impaired by low temperatures.

**Effect of Low Temperatures on Strength of Railroad Axles.** (Thos. Andrews, Proc. Inst. C. E., 1891.)—Axles 6 ft. 6 in. long between centres of journals, total length 7 ft. 3½ in., diameter at middle 4½ in., at wheel-sets 5½ in., journals 3¾ × 7 in. were tested by impact at temperatures of 0° and 100° F. Between the blows each axle was half turned over, and was also replaced for 15 minutes in the water-bath.

The mean force of concussion resulting from each impact was ascertained as follows :

Let  $h$  = height of free fall in feet,  $w$  = weight of test ball,  $hw = W =$  "energy," or work in foot-tons,  $x$  = extent of deflections between bearings,

$$\text{then } F'(\text{mean force}) = \frac{W}{x} = \frac{hw}{x}.$$

The results of these experiments show that whereas at a temperature of 0° F. a total average mean force of 179 tons was sufficient to cause the breaking of the axles, at a temperature of 100° F. a total average mean force of 428 tons was requisite to produce fracture. In other words, the resistance to concussion of the axles at a temperature of 0° F. was only about 42% of what it was at a temperature of 100° F.

The average total deflection at a temperature of 0° F. was 6.48 in., as against 15.06 in. with the axles at 100° F. under the conditions stated; this represents an ultimate reduction of flexibility, under the test of impact, of about 57% for the cold axles at 0° F., compared with the warm axles at 100° F.

**EXPANSION OF IRON AND STEEL BY HEAT.**

James E. Howard, engineer in charge of the U. S. testing-machine at Waretown, Mass., gives the following results of tests made on bars 35 inches long (*Iron Age*, April 10, 1890):

Metal.	Marks.	Chemical composition.				Coefficient of Expansion.

**DURABILITY OF IRON, CORROSION, ETC.**

**Durability of Cast Iron.**—Frederick Graff, in an article on the Philadelphia water-supply, says that the first cast-iron pipe used there was laid in 1820. These pipes were made of charcoal iron, and were in constant use for 53 years. They were uncoated, and the inside was well filled with tubercles. In salt water good cast iron, even uncoated, will last for a century at least; but it often becomes soft enough to be cut by a knife, as is shown in iron cannon taken up from the bottom of harbors after long submersion. Close-grained, hard white metal lasts the longest in sea water.—*Eng'g News*, April 23, 1887, and March 26, 1892.

**Tests of Iron after Forty Years' Service.**—A square link 12 inches broad, 1 inch thick and about 12 feet long was taken from the Kieff bridge, then 40 years old, and tested in comparison with a similar link which had been preserved in the stock-house since the bridge was built. The following is the record of a mean of four longitudinal test-pieces, 1 × 1½ × 8 inches, taken from each link (*Stahl und Eisen*, 1890):

	Old Link taken from Bridge.	New Link from Store-house.
Tensile strength per square inch, tons.....	21.8	22.2
Elastic limit .....	11.1	11.9
Elongation, per cent.....	14.05	13.42
Contraction, per cent.....	17.35	18.75

**Durability of Iron in Bridges.** (G. Lindenthal, *Eng'g*, May 2, 1884, p. 139.)—The Old Monongahela suspension bridge in Pittsburgh, built in 1845, was taken down in 1882. The wires of the cables were frequently strained to half of their ultimate strength, yet on testing them after 37 years'

use they showed a tensile strength of from 72,700 to 100,000 lbs. per square inch. The elastic limit was from 67,100 to 78,600 lbs. per square inch. Reduction at point of fracture, 35% to 75%. Their diameter was 0.13 inch.

A new ordinary telegraph wire of same gauge tested for comparison showed: T. S., of 100,000 lbs.; E. L., 81,550 lbs.; reduction, 57%. Iron rods used as stays or suspenders showed: T. S., 43,770 to 49,720 lbs. per square inch; E. L., 26,380 to 29,200. Mr. Lindenthal draws these conclusions from his tests:

“The above tests indicate that iron highly strained for a long number of years, but still within the elastic limit, and exposed to slight vibration, will not deteriorate in quality.

“That if subjected to only one kind of strain it will not change its texture, even if strained beyond its elastic limit, for many years. It will stretch and behave much as in a testing-machine during a long test.

“That iron will change its texture only when exposed to alternate severe straining, as in bending in different directions. If the bending is slight but very rapid, as in violent vibrations, the effect is the same.”

**Corrosion of Iron Bolts.**—On bridges over the Thames in London, bolts exposed to the action of the atmosphere and rain-water were eaten away in 25 years from a diameter of  $\frac{7}{8}$  in. to  $\frac{1}{2}$  in., and from  $\frac{5}{8}$  in. diameter to  $\frac{5}{16}$  inch.

Wire ropes exposed to drip in colliery shafts are very liable to corrosion.

**Corrosion of Iron and Steel.**—Experiments made at the Riverside Iron Works, Wheeling, W. Va., on the comparative liability to rust of iron and soft Bessemer steel: A piece of iron plate and a similar piece of steel, both clean and bright, were placed in a mixture of yellow loam and sand, with which had been thoroughly incorporated some carbonate of soda, nitrate of soda, ammonium chloride, and chloride of magnesium. The earth as prepared was kept moist. At the end of 33 days the pieces of metal were taken out, cleaned, and weighed, when the iron was found to have lost 0.84% of its weight and the steel 0.72%. The pieces were replaced and after 28 days weighed again, when the iron was found to have lost 2.06% of its original weight and the steel 1.79%. (*Eng'g*, June 26, 1891.)

**Corrosive Agents in the Atmosphere.**—The experiments of F. Crace Calvert (*Chemical News*, March 3, 1871) show that carbonic acid, in the presence of moisture, is the agent which determines the oxidation of iron in the atmosphere. He subjected perfectly cleaned blades of iron and steel to the action of different gases for a period of four months, with results as follows:

Dry oxygen, dry carbonic acid, a mixture of both gases, dry and damp oxygen and ammonia: no oxidation. Damp oxygen: in three experiments one blade only was slightly oxidized.

Damp carbonic acid: slight appearance of a white precipitate upon the iron, found to be carbonate of iron. Damp carbonic acid and oxygen: oxidation very rapid. Iron immersed in water containing carbonic acid oxidized rapidly.

Iron immersed in distilled water deprived of its gases by boiling rusted the iron in spots that were found to contain impurities.

**Galvanic Action** is a most active agent of corrosion. It takes place when two metals, one electro-negative to the other, are placed in contact and exposed to dampness.

Sulphurous acid (the product of the combustion of the sulphur in coal) is an exceedingly active corrosive agent, especially when the exposed iron is coated with soot. This accounts for the rapid corrosion of iron in railway bridges exposed to the smoke from locomotives. (See account of experiments by the author on action of sulphurous acid in *Jour. Frank Inst.*, June, 1875, p. 437.) An analysis of sooty iron rust from a railway bridge showed the presence of sulphurous, sulphuric, and carbonic acids, chlorine, and ammonia. Bloxam states that ammonia is formed from the nitrogen of the air during the process of rusting.

**Corrosion in Steam-boilers.**—Internal corrosion may be due either to the use of water containing free acid, or water containing sulphate or chloride of magnesium, which decompose when heated, liberating the acid, or to water containing air or carbonic acid in solution. External corrosion rarely takes place when a boiler is kept hot, but when cold it is apt to corrode rapidly in those portions where it adjoins the brickwork or where it may be covered by dust or ashes, or wherever dampness may lodge. (See *Impurities of Water*, p. 551, and *Incrustation and Corrosion*, p. 716.)

**PRESERVATIVE COATINGS.**

(The following notes have been furnished to the author by Prof. A. H. Sabin.)

**Cement.**—Iron-work is sometimes protected by bedding in concrete, in which case it is first cleaned and then washed with neat cement before being imbedded.

**Asphaltum.**—This is applied hot either by dipping (as water-pipe) or by pouring it on (as bridge floors). The asphalt should be slightly elastic when cold, with a high melting-point, not softening much at 100° F., applied at 300° to 400°; surface must be dry and should be hot; coating should be of considerable thickness.

**Paint.**—Composed of a vehicle or binder, usually linseed oil or some inferior substitute, or varnish (enamel paints); and a pigment which is a more or less inert solid in the form of powder, either mixed or ground together. The principal pigments are white lead (carbonate) and white zinc (oxide), red lead (peroxide), oxides of iron, hydrated and dehydrated, graphite, lamp-black, chrome yellow, ultramarine and Prussian blue, and various tinting colors. White lead has the greatest body or opacity of white pigments; three coats of it equal five of white zinc; zinc is more brilliant and permanent, but it is liable to peel, and it is customary to mix the two. These are the standard white paints for all uses and the basis of all light-colored paints. Anhydrous iron oxides are brown and purplish brown, hydrated iron oxides are yellowish red to reddish yellow, with more or less brown; most iron oxides are mixtures of both sorts. They also contain frequently manganese and clay. They are cheap, and are serviceable paints for wood, and are often used on iron, but for the latter use are falling into disrepute. Graphite used for painting iron contains from 10 to 90% foreign matter, usually silicates and iron oxides. It is very opaque, hence has great covering power, and may be applied in a very thin coat which should be avoided. It retards the drying of oil, hence the necessity of using dryers; these are lead and manganese compounds dissolved in oil and turpentine or benzine, and act as carriers of oxygen; they are necessary in most paints, but should be used as little as possible. There are many grades of lamp-black; as a rule the cheaper sorts contain oily matter and are especially hard to dry; all lamp-black is slow to dry in oil. It is the principal black on wood, and is used some on iron, usually in combination with varnish or varnish-like compounds. It is very permanent on wood. A gallon of oil takes only a pound of lamp-black to make a paint, while the same amount of oil requires about 40 lbs. of red lead. On this account red-lead paint, which weighs about 30 lbs. per gallon, is the most expensive of all common paints. It does not dry slowly like other oil paints, but combines with the oil to make a sort of cement; on this account it is used on the joints of steam-pipes, etc. To prevent the mixture of red lead and oil setting into a cake, and also to cheapen it, it is often adulterated with whiting or sometimes with white zinc, the proportion of adulterant being sometimes double the lead. Red lead has long had a high reputation as a paint for iron and steel and is still used very extensively; but of late years some of the new paints and varnish-like preparations have displaced it to some extent even on the most important work.

**Varnishes.**—These are made by melting fossil resin, to which is then added from half its weight to three times its weight of refined linseed oil, and the compound is thinned with turpentine; they usually contain a little dryer. They are chiefly used on wood, being more durable and more brilliant than oil, and are often used over paint to preserve it. Asphaltum is sometimes substituted in part or in whole for the fossil resin, and in this way are made varnishes which have been applied to iron and steel with good results. Asphaltum and animal and vegetable tar and pitch have also been simply dissolved in solvents, as benzine or carbon disulphide, and used for the same purpose.

All these preservative coatings are supposed to form impervious films, keeping out air and moisture; but in fact all are somewhat porous. On this account it is necessary to have a film of appreciable thickness, best formed by successive coats, so that the pores of one will be closed by the next. The pigment is used to give an agreeable color, to help fill the pores of the oil film, to make the paint harder so that it will resist abrasion, and to make a thicker film. In varnishes these results are sought to be attained by the resin which is dissolved in the oil. There is no sort of agreement among

practical men as to which is the best coating for any particular case; this is probably because so much depends on the preparation of the surface and the care with which the coating is applied, and also because the conditions of exposure vary so greatly.

**Methods of Application.**—Too much care cannot be given to the preparation of the surface. If it is wood, it should be dry, and the surface of knots should be coated with some preparation which will keep the tarry matter in the wood from the coating. All old paint or varnish should be removed by burning and scraping. Metallic surfaces should be cleaned by wire brushes and scrapers, and if the permanence of the work is of much importance the scale and oxide should be completely removed by acid pickling or by the sand-blast or some equally efficient means. Pickling is usually done with a 10% solution of sulphuric acid; as the solution becomes exhausted it may be made more active by heating. All traces of acid must be removed by washing and the metal must be rapidly dried and painted before it becomes in the slightest degree oxidized. The sand-blast, which has been applied to large work recently and for many years to small work with good results, leaves the surface perfectly clean and dry; the paint must be applied immediately. Plenty of time should always be allowed, usually about a week, for each coat of paint to dry before the next coat is applied; less than two coats should never be used. Two will last three times as long as one coat. Benzine should not be an ingredient in coatings for iron-work, because its rapid evaporation lowers the temperature of the iron and may cause formation of dew on the surface adjacent to the paint which is immediately to be painted.

Cast-iron water-pipes are usually coated by dipping in a hot mixture of coal-tar and coal-tar pitch; riveted steel pipes by dipping in hot asphalt or by a japan enamel which is baked on at about 400° F. Sliips' bottoms are usually coated with some sort of paint to prevent rusting, over which is spread, hot, a poisonous, slowly soluble compound, usually a copper soap, to prevent adhesion of marine growths.

Galvanized-iron and tin surfaces should be thoroughly cleaned with benzine and scrubbed before painting. When new they are covered with grease and chemicals used in coating the plates, and these must be removed or the paint will be destroyed.

**Quantity of Paint for a Given Surface.**—One gallon of paint will cover 250 to 350 sq. ft. as a first coat, depending on the character of the surface, and from 350 to 450 sq. ft. as a second coat.

**Qualities of Paints.**—*The Railroad and Engineering Journal*, vols. liv and lv, 1890 and 1891, has a series of articles on paint as applied to *wooden structures*, its chemical nature, application, adulteration, etc., by Dr. C. B. Dudley, chemist, and F. N. Pease, assistant chemist, of the Penna. R. R. They give the results of a long series of experiments on paint as applied to railway purposes.

**Rustless Coatings for Iron and Steel.**—Tinning, enamelling, lacquering, galvanizing, electro-chemical painting, and other preservative methods are discussed in two important papers by M. P. Wood, in *Trans. A. S. M. E.*, vols. xv and xvi.

**A Method of Producing an Inoxidizable Surface on iron and steel** by means of electricity has been developed by M. A. de Meritens (*Engineering*). The article to be protected is placed in a bath of ordinary or distilled water, at a temperature of from 158° to 176° F., and an electric current is sent through. The water is decomposed into its elements, oxygen and hydrogen, and the oxygen is deposited on the metal, while the hydrogen appears at the other pole, which may either be the tank in which the operation is conducted or a plate of carbon or metal. The current has only sufficient electromotive force to overcome the resistance of the circuit and to decompose the water; for if it be stronger than this, the oxygen combines with the iron to produce a pulverulent oxide, which has no adherence. If the conditions are as they should be, it is only a few minutes after the oxygen appears at the metal before the darkening of the surface shows that the gas has united with the iron to form the magnetic oxide  $Fe_3O_4$ , which will resist the action of the air and protect the metal beneath it. After the action has continued an hour or two the coating is sufficiently solid to resist the scratch-brush, and it will then take a brilliant polish.

If a piece of thickly rusted iron be placed in the bath, its sesquioxide ( $Fe_2O_3$ ) is rapidly transformed into the magnetic oxide. This outer layer

has no adhesion, but beneath it there will be found a coating which is actually a part of the metal itself.

In the early experiments M. de Meritens employed pieces of steel only, but in wrought and cast iron he was not successful, for the coating came off with the slightest friction. He then placed the iron at the negative pole of the apparatus, after it had been already applied to the positive pole. Here the oxide was reduced, and hydrogen was accumulated in the pores of the metal. The specimens were then returned to the anode, when it was found that the oxide appeared quite readily and was very solid. But the result was not quite perfect, and it was not until the bath was filled with distilled water, in place of that from the public supply, that a perfectly satisfactory result was attained.

**Manganese Plating of Iron as a Protection from Rust.**

--According to the Italian *Progresso*, articles of iron can be protected against rust by sinking them near the negative pole of an electric bath composed of 10 litres of water, 50 grammes of chloride of manganese, and 200 grammes of nitrate of ammonium. Under the influence of the current the bath deposits on the articles a protecting film of metallic manganese.

**A Non-oxidizing Process of Annealing** is described by H. P. Jones, in *Eng'g News*, Jan. 2, 1892. The new process uses a non-oxidizing gas, and is the invention of Mr. Horace K. Jones, of Hartford, Conn. Its principal feature consists in keeping the annealing retort in communication with the gas-holder or gas-main during the entire process of heating and cooling, the gas thus being allowed to expand back into the main, and being, therefore, kept at a practically constant pressure.

The retorts are made from wrought-iron tubes. The gas is taken directly from the mains supplying the city with illuminating gas. If metal which has been blued or slightly oxidized is subjected to the annealing process it comes out bright, the oxide being reduced by the action of the gas.

Comparative tests were made of specimens of steel wire annealed in illuminating gas, in nitrogen, and in an open fire and cooled in ashes, and of specimens of the unannealed metal. The wires were .188 in. in diameter and were turned down to .150 in.

The average results were as follows:

Unannealed, two lots, 5 pieces each, tensile strength av. 97,120 and 80,790 lbs. per sq. in., elongation 7.12% and 8.80%. Annealed in open fire, 8 tests, av. t. s. 63,090, el. 26.76%. Annealed in nitrogen, av. of 3 lots, 13 pieces, t. s. 59,820, el. 29.33%. Annealed in illuminating gas, av. of 3 lots, 13 pieces, t. s. 60,180, el. 28.29%. The elongations are referred to an original length of 1.15 ins.

**STEEL.**

**RELATION BETWEEN THE CHEMICAL COMPOSITION AND PHYSICAL CHARACTER OF STEEL.**

W. R. Webster (see *Trans. A. I. M. E.*, vols. xxi and xxii, 1893-4) gives results of several hundred analyses and tensile tests of basic Bessemer steel plates, and from a study of them draws conclusions as to the relation of chemical composition to strength, the chief of which are condensed as follows:

The indications are that a pure iron, without carbon, phosphorus, manganese, silicon, or sulphur, if it could be obtained, would have a tensile strength of 34,750 lbs. per square inch, if tested in a 3/8-inch plate. With this as a base, a table is constructed by adding the following hardening effects, as shown by increase of tensile strength, for the several elements named.

Carbon, a constant effect of 800 lbs. for each 0.01%.

Sulphur, " " 500 " " 0.01%.

Phosphorus, the effect is higher in high-carbon than in low-carbon steels.

With carbon hundredths %... 9 10 11 12 13 14 15 16 17

Each .01% P has an effect of lbs. 900 1000 1100 1200 1300 1400 1500 1500 1500

-Manganese, the effect decreases as the per cent of manganese increases.

Mn being per cent.....	{	.00	.15	.20	.25	.30	.35	.40	.45	.50	.55
		to									
		.15	.20	.25	.30	.35	.40	.45	.50	.55	.65

Str'gth increases for .01% 240 240 220 200 180 160 140 120 100 100 lbs.

Total incr. from 0 Mn... 3600 4800 5900 6900 7800 8600 9300 9900 10,400 11,400

Silicon is so low in this steel that its hardening effect has not been considered.

With the above additions for carbon and phosphorus the following table has been constructed (abridged from the original by Mr. Webster). To the figures given the additions for sulphur and manganese should be made as above.

**Estimated Ultimate Strengths of Basic Bessemer Steel Plates.**

For Carbon, .06 to .24; Phosphorus, .00 to .10; Manganese and Sulphur, .00 in all cases.

Carbon.	.06	.08	.10	.12	.14	.16	.18	.20	.22	.24

In all rolled steel the quality depends on the size of the bloom or ingot from which it is rolled, the work put on it, and the temperature at which it is finished, as well as the chemical composition.

The above table is based on tests of plates 3/8 inch thick and under 70 inches wide; for other plates Mr. Webster gives the following corrections for thickness and width. They are made necessary only by the effect of thickness and width on the finishing temperature in ordinary practice. Steel is frequently spoiled by being finished at too high a temperature.

**Corrections for Size of Plates.**

Plates. Inches thick.	Up to 70 ins. wide.		Over 70 ins. wide.	
	Lbs.		Lbs.	
3/4 and over.....	— 2000		— 1000	
11/16 "	— 1750		— 750	
5/8 "	— 1500		— 500	
9/16 "	— 1250		— 250	
1/2 "	— 1000		— 0	
7/16 "	— 500		± 500	
3/8 "	0		+ 1000	
5/16 "	+ 3000		+ 5000	

Comparing the actual result of tests of 408 plates with the calculated results, Mr. Webster found the variation to range as in the table below.

**Summary of the Differences Between Calculated and Actual Results in 408 Tests of Plate Steel.**

In the first three columns the effects of sulphur were not considered; in the last three columns the effect of sulphur was estimated at 500 lbs. for each .01% of S.

	Universal Mill.	Sheared.	Both Mills.	Universal Mill.	Sheared.	Both Mills.	Both Mills, Corrected for Thickness and Width.
Per cent within 1000 lbs..	23.4	32.1	28.4	24.6	27.0	26.0	28.4
" " " 2000 "	40.9	48.9	45.6	48.5	54.9	52.2	55.1
" " " 3000 "	62.5	71.3	67.6	67.8	73.0	70.8	74.7
" " " 4000 "	75.5	81.0	78.7	82.5	85.2	84.1	89.9
" " " 5000 "	89.5	91.1	90.4	93.0	92.8	92.9	94.9

The last figure in the table would indicate that if specifications were drawn calling for steel plates not to vary more than 5000 lbs. T. S. from a specified figure (equal to a total range of 10,000 lbs.), there would be a probability of the rejection of 5% of the blooms rolled, even if the whole lot was made from steel of identical chemical analysis. In 1000 heats only 2% of the heats failed to meet the requirements of the orders on which they were graded; the loss of plates was much less than 1%, as one plate was rolled from each heat and tested before rolling the remainder of the heat.

R. A. Hadfield (*Jour. Iron and Steel Inst.*, No. 1, 1894) gives the strength of very pure Swedish iron, remelted and tested as cast, 20.1 tons (45,024 lbs.) per sq. in.; remelted and forged, 21 tons (47,040 lbs.). The analysis of the cast bar was: C, 0.08; Si, 0.01; S, 0.02; P, 0.02; Mn, 0.01; Fe, 99.82.

**Effect of Oxygen upon Strength of Steel.**—A. Lantz, of the Peine works, Germany, in a letter to Mr. Webster, says that oxygen plays an important rôle—such that, given a like content of carbon, phosphorus, and manganese, a blow with greater oxygen content gives a greater hardness and less ductility than a blow with less oxygen content. The method used for determining oxygen is that of Prof. Ledebur, given in *Stahl und Eisen*, May, 1892, p. 193. The variation in oxygen may make a difference in strength of nearly ½ ton per sq. in. (*Jour. Iron and Steel Inst.*, No. 1, 1894.)

**RANGE OF VARIATION IN STRENGTH OF BESSEMER AND OPEN-HEARTH STEELS.**

The Carnegie Steel Co. in 1888 published a list of 1057 tests of Bessemer and open-hearth steel, from which the following figures are selected :

Kind of Steel.	No. of Tests.	Elastic Limit.		Ultimate Strength.		Elongation per cent in 8 inches.	
		High't.	Lowest	High't.	Lowest	High't.	Lowest
(a) Bess. structural...	100	46,570	39,230	71,300	61,450	33.00	23.75
(b) " " .....	170	47,690	39,970	73,540	65,200	30.25	23.15
(c) Bess. angles.....	72	41,890	32,630	63,450	56,130	34.30	26.25
(d) O. H. fire-box....	25	.....	.....	62,790	50,350	36.00	25.62
(e) O. H. bridge.....	20	.....	.....	69,940	63,970	30.00	22.75

REQUIREMENTS OF SPECIFICATIONS.

- (a) Elastic limit, 35,000; tensile strength, 62,000 to 70,000; elong. 22% in 8 in.
- (b) Elastic limit, 40,000; tensile strength, 67,000 to 75,000.
- (c) Elastic limit, 30,000; tensile strength, 56,000 to 64,000; elong. 20% in 8 in.
- (d) Tensile strength 50,000 to 62,000; elong. 26% in 4 in.
- (e) Tensile strength, 64,000 to 70,000; elong. 20% in 8 in.

**Strength of Open-hearth Structural Steel.** (Pencoyd Iron Works.)—As a general rule, the percentage of carbon in steel determines its hardness and strength. The higher the carbon the harder the steel, the higher the tenacity, and the lower the ductility will be. The following list exhibits the average physical properties of good open-hearth basic steel :

Per cent Carbon.	Ultimate Strength, lbs. per sq. in.	Elastic Limit, lbs. per sq. in.	Stretch in 8 in., %.	Red. of Area, %.	Per cent Carbon.	Ultimate Strength, lbs. per sq. in.	Elastic Limit, lbs. per sq. in.	Stretch in 8 in., %.	Red. of Area, %.
.08	54000	32500	32	60	.17	61600	37000	27	50
.09	54800	33000	31	58	.18	62500	37500	27	49
.10	55700	33500	31	57	.19	63300	38000	26	48
.11	56500	34000	30	56	.20	64200	38500	26	47
.12	57400	34500	30	55	.21	65000	39000	25	46
.13	58200	35000	29	54	.22	65800	39500	25	45
.14	59100	35500	29	53	.23	66600	40000	24	44
.15	60000	36000	28	52	.24	67400	40500	24	43
.16	60800	36500	28	51	.25	68200	41000	23	42

The coefficient of elasticity is practically uniform for all grades, and is the same as for iron, viz., 29,000,000 lbs. These figures form the average of a numerous series of tests from rolled bars, and can only serve as an ap-

proximation in single instances, when the variation from the average may be considerable. Steel below .10 carbon should be capable of doubling flat without fracture, after being chilled from a red heat in cold water. Steel of .15 carbon will occasionally submit to the same treatment, but will usually bend around a curve whose radius is equal to the thickness of the specimen; about 90% of specimens stand the latter bending test without fracture. As the steel becomes harder its ability to endure this bending test becomes more exceptional, and when the carbon ratio becomes .20, little over 25% of specimens will stand the last-described bending test. Steel having about .40% carbon will usually harden sufficiently to cut soft iron and maintain an edge.

Mehrtens gives the following tables in *Stahl und Eisen* (*Iron Age*, April 20, 1893) showing the range of variation in strength, etc., of basic Bessemer and of basic open-hearth structural steel. The figures in the columns headed Per Cent show the per cent of the total number of charges which came within the range given.

BASIC BESSEMER STEEL, 680 CHARGES.

44,100 to 48,400.....	8.5	62,600 to 65,100.....	9.4	30 to 37.1.....	24.3

Rivet steel, 19 charges, showed a total range from 51,800 to 56,900 lbs. tensile strength, and 25.2 to 29.8 per cent elongation.

In the basic Bessemer steel over 90% was below 0.08 phosphorus, and all were below 0.10; manganese was below 0.6 in over 90%, and below 0.9 in all, sulphur was below 0.05 in 84%, the maximum being 0.071; carbon was below 0.10, and silicon below 0.01 in all. In the basic open-hearth steel phosphorus was below 0.06 in 96%, the maximum being 0.08; manganese below 0.50 in 97%; sulphur below 0.07 in 88%, the maximum being 0.12. The carbon ranged from 0.09 to 0.14.

**Low Tensile Strength of Very Pure Steel.**—Swedish nail-rod open-hearth steel, tested by the author in 1881, showed a tensile strength of only 42,591 lbs. per sq. in. A piece of American nail-rod steel showed 45,021 lbs. per sq. in. Both steels contained about .10 carbon and .015 phosphorus, and were very low in sulphur, manganese, and silicon. The pieces tested were bars about  $2 \times \frac{3}{8}$  in. section.

**Low Strength Due to Insufficient Work.** (A. E. Hunt, *Trans. A. I. M. E.*, 1886.)—Soft steel ingots, made in the ordinary way for boiler plates, have only from 10,000 to 20,000 lbs. tensile strength per sq. in., an elongation of only about 10% in 8 in., and a reduction of area of less than 20%. Such ingots, properly heated and rolled down from 10 in. to  $\frac{1}{2}$  in. thickness, will give from 55,000 to 65,000 lbs. tensile strength, an elongation in 8 in. of from 23% to 33%, and a reduction of area of from 55% to 70%. Any work stopping short of the above reduction in thickness ordinarily yields intermediate results in its tensile tests.

**Effect of Finishing Temperature in Rolling.**—The strength and ductility of steel depend to a high degree upon fineness of grain, and this may be obtained by having the temperature of the steel rather low, say at a dull red heat, 1300° to 1400° F., during the finishing stage of rolling. In the manufacture of steel rails a great improvement in quality has been obtained by finishing at a low temperature. An indication of the finishing temperature is the amount of shrinkage by cooling after leaving the rolls. The Philadelphia and Reading Railway Company's specification for rails (1902) says, "The temperature of the ingot or bloom shall be such that with rapid rolling and without holding before or in the finishing passes or subsequently, and without artificial cooling after leaving the last pass, the distance between hot saws shall not exceed 30 ft. 6 in. for a 30-ft. rail."

**Fining the Grain by Annealing.**—Steel which is coarse-grained

on account of leaving the rolls at too high a temperature may be made fine-grained and have its ductility greatly increased without lowering its tensile strength by reheating to a cherry red and cooling at once in air. (See paper on "Steel Rails," by Robert Job, Trans. A. I. M. E., 1902.)

**Effect of Cold Rolling.**—Cold rolling of iron and steel increases the elastic limit and the ultimate strength, and decreases the ductility. Major Wade's experiments on bars rolled and polished cold by Lauth's process showed an average increase of load required to give a slight permanent set as follows: Transverse, 162%; torsion, 130%; compression, 161% on short columns 1½ in. long, and 64% on columns 8 in. long; tension, 95%. The hardness, as measured by the weight required to produce equal indentations, was increased 50%; and it was found that the hardness was as great in the centre of the bars as elsewhere. Sir W. Fairbairn's experiments showed an increase in ultimate tensile strength of 50%, and a reduction in the elongation in 10 in. from 2 in. or 20%, to 0.79 in. or 7.9%.

**Hardening of Soft Steel.**—A. E. Hunt (Trans. A. I. M. E., 1883, vol. xii), says that soft steel, no matter how low in carbon, will harden to a certain extent upon being heated red-hot and plunged into water, and that it hardens more when plunged into brine and less when quenched in oil.

An illustration was a heat of open-hearth steel of 0.15% carbon and 0.29% of manganese, which gave the following results upon test-pieces from the same ¼ in. thick plate.

	Maximum Load. lbs. per sq. in.	Elongation in 8 in. Per cent.	Reduction of Area. Per cent.
Unhardened....	55,000	27	62
Hardened in water.....	74,000	25	50
Hardened in brine.....	84,000	22	43
Hardened in oil.....	67,700	26	49

While the ductility of such hardened steel does not decrease to the extent that the increased tenacity would indicate, and is much superior to that of normal steel of the high tenacity, still the greatly increased tenacity after hardening indicates that there must be a considerable molecular change in the steel thus hardened, and that if such a hardening should be created locally in a steel plate, there must be very dangerous internal strains caused thereby.

**Comparison of Tests of Full-size Eye-bars and Sample Test-pieces of Same Steel Used in the Memphis Bridge.**

(Geo. S. Morison, Trans. A. S. C. E., 1893.)

Full-Sized Eyebars, Sections 10" wide × 1 to 2 3/16" thick.					Sample Bars from Same Melts, about 1 in. area.

10.3	11.8	12.3	33,360	73,550	51.5	25.5	40,410	69,900
44.6	32.0	15.7	32,520	60,710	43.6	27.0	40,400	70,490
46.0	35.8	14.9	28,000	58,720	44.4	29.5	40,000	66,800
41.8	23.5	13.1	32,290	62,270	42.8	21.3	40,530	72,240
41.2	47.1	15.1	29,970	58,680	45.7	27.0	40,610	70,480

The average strength of the full-sized eye-bars was about 8000 lbs. per sq. in., or about 12% less than that of the sample test-pieces.

## TREATMENT OF STRUCTURAL STEEL.

(James Christie, Trans. A. S. C. E., 1893.)

**Effect of Punching and Shearing.**—There is no doubt that steel of higher tensile strength than is now accepted for structural purposes should not be punched or sheared, or that the softer material may contain elements prejudicial to its use however treated, but especially if punched. But extensive evidence is on record indicating that steel of good quality, in bars of moderate thickness and below or not much exceeding 80,000 lbs. tensile strength, is not any more, and frequently not as much, injured as wrought iron by the process of punching or shearing.

The physical effects of punching and shearing as denoted by tensile test are for iron or steel:

Reduction of ductility; elevation of tensile strength at elastic limit; reduction of ultimate tensile strength.

In very thin material the superficial disturbance described is less than in thick; in fact, a degree of thinness is reached where this disturbance practically ceases. On the contrary, as thickness is increased the injury becomes more evident.

The effects described do not invariably ensue; for unknown reasons there are sometimes marked deviations from what seems to be a general result.

By thoroughly annealing sheared or punched steels the ductility is to a large extent restored and the exaggerated elastic limit reduced, the change being modified by the temperature of reheating and the method of cooling.

It is probable that the best results combined with least expenditure can be obtained by punching all holes where vital strains are not transferred by the rivets; and by reaming for important joints where strains on riveted joints are vital, or wherever perforation may reduce sections to a minimum. The reaming should be sufficient to thoroughly remove the material disturbed by punching; to accomplish this it is best to enlarge punched holes at least  $\frac{1}{8}$  in. diameter with the reamer.

**Riveting.**—It is the current practice to perforate holes  $\frac{1}{16}$  in. larger than the rivet diameter. For work to be reamed it is also a usual requirement to punch the holes from  $\frac{1}{8}$  to  $\frac{3}{16}$  in. less than the finished diameter, the holes being reamed to the proper size after the various parts are assembled.

It is also excellent practice to remove the sharp corner at both ends of the reamed holes, so that a fillet will be formed at the junction of the body and head of the finished rivets.

The rivets of either iron or mild steel should be heated to a bright red or yellow heat and subjected to a pressure of not less than 50 tons per square inch of sectional area.

For rivets of ordinary length this pressure has been found sufficient to completely fill the hole. If, however, the holes and the rivets are exceptionally long, a greater pressure and a slower movement of the closing tool than is used for shorter rivets has been found advantageous in compelling the more sluggish flow of the metal throughout the longer hole.

**Welding.**—No welding should be allowed on any steel that enters into structures.

**Upsetting.**—Enlarged ends on tension bars for screw-threads, eyebars, etc., are formed by upsetting the material. With proper treatment and a sufficient increment of enlarged sectional area over the body of the bar the result is entirely satisfactory. The upsetting process should be performed so that the properly heated metal is compelled to flow without folding or lapping.

**Annealing.**—The object of annealing structural steel is for the purpose of securing homogeneity of structure that is supposed to be impaired by unequal heating, or by the manipulation necessarily attendant on certain processes. The objects to be annealed should be heated throughout to a uniform temperature and uniformly cooled.

The physical effects of annealing, as indicated by tensile tests, depend on the grade of steel, or the amount of hardening elements associated with it; also on the temperature to which the steel is raised, and the method or rate of cooling the heated material.

The physical effects of annealing medium-grade steel, as indicated by tensile test, are reported very differently by different observers, some claiming directly opposite results from others. It is evident, when all the attendant conditions are considered, that the obtained results must vary both in kind and degree.

The temperatures employed will vary from 1000° to 1500° F.; possibly even a wider range is used. In some cases the heated steel is withdrawn at full temperature from the furnace and allowed to cool in the atmosphere; in others the mass is removed from the furnace, but covered under a muffle, to lessen the free radiation; or, again, the charge is retained in the furnace, and the whole mass cooled with the furnace, and more slowly than by either of the other methods.

The best general results from annealing will probably be obtained by introducing the material into a uniformly-heated oven in which the temperature is not so high as to cause a possibility of cracking by sudden and unequal changing of temperature, then gradually raising the temperature of the material until it is uniformly about 1200° F., then withdrawing the material after the temperature is somewhat reduced and cooling under shelter of a muffle, sufficiently to prevent too free and unequal cooling on the one hand or excessively slow cooling on the other.

G. G. Mehlertens, Trans. A. S. C. E. 1893, says: "Annealing is of advantage to all steel above 64,000 lbs. strength per square inch, but it is questionable whether it is necessary in softer steels. The distortions due to heating cause trouble in subsequent straightening, especially of thin plates.

"In a general way all unannealed mild steel for a strength of 56,000 to 64,000 lbs. may be worked in the same way as wrought iron. Rough treatment or working at a blue heat must, however, be prohibited. Shearing is to be avoided, except to prepare rough plates, which should afterwards be smoothed by machine tools or files before using. Drifting is also to be avoided, because the edges of the holes are thereby strained beyond the yield point. Reaming drilled holes is not necessary, particularly when sharp drills are used and neat work is done. A slight countersinking of the edges of drilled holes is all that is necessary. Working the material while heated should be avoided as far as possible, and the engineer should bear this in mind when designing structures. Upsetting, cranking, and bending ought to be avoided, but when necessary the material should be annealed after completion.

"The riveting of a mild-steel rivet should be finished as quickly as possible, before it cools to the dangerous heat. For this reason machine work is the best. There is a special advantage in machine work from the fact that the pressure can be retained upon the rivet until it has cooled sufficiently to prevent elongation and the consequent loosening of the rivet."

**Punching and Drilling of Steel Plates.** (Proc. Inst. M. E., Aug. 1887, p. 326.)—In Prof. Unwin's report the results of the greater number of the experiments made on iron and steel plates lead to the general conclusion that, while thin plates, even of steel, do not suffer very much from punching, yet in those of  $\frac{1}{2}$  in. thickness and upwards the loss of tenacity due to punching ranges from 10% to 23% in iron plates and from 11% to 33% in the case of mild steel. Mr. Parker found the loss of tenacity in steel plates to be as high as fully one third of the original strength of the plate. In drilled plates, on the contrary, there is no appreciable loss of strength. It is even possible to remove the bad effects of punching by subsequent reaming or annealing.

**Working Steel at a Blue Heat.**—Not only are wrought iron and steel much more brittle at a blue heat (i.e., the heat that would produce an oxide coating ranging from light straw to blue on bright steel, 430° to 600° F.), but while they are probably not seriously affected by simple exposure to blueness, even if prolonged, yet if they be worked in this range of temperature they remain extremely brittle after cooling, and may indeed be more brittle than when at blueness; this last point, however, is not certain. (Howe, "Metallurgy of Steel," p. 534.)

Tests by Prof. Krohn, for the German State Railways, show that working at blue heat has a decided influence on all materials tested, the injury done being greater on wrought iron and harder steel than on the softer steel. The fact that wrought iron is injured by working at a blue heat was reported by Stromeyer. (*Engineering News*, Jan. 9, 1892.)

A practice among boiler-makers for guarding against failures due to working at a blue heat consists in the cessation of work as soon as a plate which had been red-hot becomes so cool that the mark produced by rubbing a hammer-handle or other piece of wood will not glow. A plate which is not hot enough to produce this effect, yet too hot to be touched by the hand, is most probably blue hot, and should under no circumstances be hammered or bent. (C. E. Stromeyer, Proc. Inst. C. E. 1886.)

**Welding of Steel.**—A. E. Hunt (A. I. M. E., 1892) says: I have never seen so-called "welded" pieces of steel pulled apart in a testing-machine or

otherwise broken at the joint which have not shown a smooth cleavage-plane, as it were, such as in iron would be condemned as an imperfect weld. My experience in this matter leads me to agree with the position taken by Mr. William Metcalf in his paper upon Steel in the *Trans. A. S. C. E.*, vol. xvi., p. 301. Mr. Metcalf says, "I do not believe steel can be welded."

**Oil-tempering and Annealing of Steel Forgings.**—H. F. J. Porter says (1897) that all steel forgings above 0.1% carbon should be annealed, to relieve them of forging and annealing strains, and that the process of annealing reduces the elastic limit to 47% of the ultimate strength. Oil-tempering should only be practised on thin sections, and large forgings should be hollow for the purpose. This process raises the elastic limit above 50% of the ultimate tensile strength, and in some alloys of steel, notably nickel steel, will bring it up to 60% of the ultimate.

**Hydraulic Forging of Steel.** (See pages 618 and 619.)

### INFLUENCE OF ANNEALING UPON MAGNETIC CAPACITY.

Prof. D. E. Hughes (*Eng'g*, Feb. 8, 1884, p. 130) has invented a "Magnetic Balance," for testing the condition of iron and steel, which consists chiefly of a delicate magnetic needle suspended over a graduated circular index, and a magnet coil for magnetizing the bar to be tested. He finds that the following laws hold with every variety of iron and steel:

1. The magnetic capacity is directly proportional to the softness, or molecular freedom.

2. The resistance to a feeble external magnetizing force is directly as the hardness, or molecular rigidity.

The magnetic balance shows that annealing not only produces softness in iron, and consequent molecular freedom, but it entirely frees it from all strains previously introduced by drawing or hammering. Thus a bar of iron drawn or hammered has a peculiar structure, say a fibrous one, which gives a greater mechanical strength in one direction than another. This bar, if thoroughly annealed at high temperatures, becomes homogeneous in all directions, and has no longer even traces of its previous strains, provided that there has been no actual separation into a distinct series of fibres.

### Effect of Annealing upon the Magnetic Capacity of Different Wires; Tests by the Magnetic Balance.

Description.	Magnetic Capacity.	
	Bright as sent.	Annealed.
	deg. on scale.	deg. on scale.

## STANDARD SPECIFICATIONS FOR STEEL.

The following specifications are abridged from those adopted Aug. 10, 1901, by the American Section of the International Association for Testing Materials.\*

**Kinds of Steel Used for Different Purposes.**—O, open-hearth; B, Bessemer; C, crucible.

(1) *Castings*, O, B, C. (2) *Axles*, O. (3) *Forgings*, O, B, C. (4) *Tires*, O, C. (5) *Rails*, O, B. (6) *Splice-bars*, O, B. (7) *Structural Steel for buildings*, O, B. (8) *Structural steel for ships*, O. (9) *Boiler-plate and rivets*, O.

## CHEMICAL REQUIREMENTS FOR THE ABOVE NINE CLASSES.

(The minus sign after the figures means "or less.")

(1) ordinary, P, 0.08—; C, 0.40—; tested castings, P, 0.05—; S, 0.05—. (2) P, 0.06—; S, 0.06—. Nickel steel, Ni, 3.00 to 4.00; P, 0.04—; S, 0.04—. (3) soft or low carbon, P, 0.10—; S, 0.10—; Class B (see below), P, 0.06—; S, 0.06—. Classes C and D, P, 0.04—; S, 0.04—. (4) P, 0.05—; S, 0.05—; Mn, 0.80—; Si, 0.20+. (5) P, 0.10—; Si, 0.20—; C, *a*, 0.35 to 0.45; *b*, 0.38 to 0.48; *c*, 0.40 to 0.50; *d*, 0.43 to 0.53; *e*, 0.45 to 0.55; Mn, *a, b*, 0.70 to 1.00; *c*, 0.75 to 1.05; *d, e*, 0.80 to 1.10. [*a*, 50 to 59+ lbs. per yard; *b*, 60 to 69+ lbs.; *c*, 70 to 79+ lbs.; *d*, 80 to 89+ lbs.; *e*, 90 to 100 lbs.] (6) P, 0.10—; C, 0.15—; Mn, 0.30 to 0.60. (7) P, 0.10—. (8) acid, P, 0.08—; S, 0.06—; basic, P, 0.06—; S, 0.06—. (9) *a*, P, 0.06—; *b, c, e*, P, 0.04—; *d*, P, 0.03—; *a, b, S*, 0.05—; Mn, 0.30 to 0.60; *c, d, e*, S, 0.04—; Mn, 0.30 to 0.50. [*a*, flange or boiler steel, acid; *b*, do. basic; *c*, fire-box, acid; *d*, do. basic; *e*, extra soft.]

"Where the physical properties desired are clearly and properly specified, the chemistry of the steel, other than prescribing the limits of the injurious impurities, P and S, may in the present state of the art of making steel be safely left to the manufacturer."

## PHYSICAL REQUIREMENTS.

(1) **Castings** subjected to physical tests.

Quality.	Hard.	Medium.	Soft.
Tensile strength, lbs. per sq. in. ....	85,000	70,000	60,000
Yield-point, lbs. per sq. in. ....	38,250	31,500	27,000
Elongation, per cent in 2 ins. ....	15	18	22
Contr. of area, per cent. ....	20	25	30

The above are the minimum requirements. Test-piece  $\frac{1}{2}$  in. diam. **Bending test:** Specimen  $1 \times 1\frac{1}{2}$  ins. to bend cold around a diam. of 1 in. through  $120^\circ$  for soft and  $90^\circ$  for medium castings.

(2) **Axles.**—For car, engine-truck, and tender-truck axles no tensile test is required. For driving-axles, minimum requirements: T. S. 80,000; Y. P. 40,000 for carbon steel (*a*), 50,000 for nickel steel, 3 to 4 per cent Ni, oil-tempered or annealed (*b*). Elongation in 2 ins., 18 per cent for *a*, 25 per cent for *b*. Contraction of area, 45 per cent for *b*. Test-piece  $\frac{1}{2}$  in. diam.

**Drop-test.**—Not required for driving-axles. For other axles one axle from each melt to be tested on a standard R.R. drop-testing apparatus, with supports 3 ft. apart, tup 1640 lbs., anvil 17,500 lbs., supported on springs. The axle shall stand the number of blows named below without rupture and without exceeding at the first blow the deflection stated. It is to be turned over after the first, third, and fifth blows.

Diam. of axle at centre, ins. . . . .	4 $\frac{1}{4}$	4 $\frac{3}{8}$	4 $\frac{7}{16}$	4 $\frac{5}{8}$	4 $\frac{3}{4}$	5 $\frac{3}{8}$	5 $\frac{7}{8}$
No. of blows . . . . .	5	5	5	5	5	5	7
Height of drop, ft. . . . .	24	26	28 $\frac{1}{2}$	31	34	43	43
Deflection, ins. . . . .	8 $\frac{1}{4}$	8 $\frac{1}{4}$	8 $\frac{1}{4}$	8	8	7	5 $\frac{1}{2}$

(3) **Steel Forgings.**—Classification: A, soft or low carbon; B, carbon steel, not annealed; C, do., annealed; D, do., oil-tempered; E, nickel-steel, annealed; F, do., oil-tempered. Sub-classes: *a*, solid or hollow forgings, diam. or thickness not over 10 ins.; *b*, solid forgings, diam. not over 20 ins., or thickness of section not over 15 ins.; *c*, solid, over 20 ins. diam.; *d*, solid

\*The complete specifications may be found in book form in "American Standard Specifications for Steel," by Albert Ladd Colby (Chemical Publishing Co., Easton, Pa., 1902).

or hollow, diam. or thickness not over 3 ins.; *e*, do., not over 6 ins. Minimum requirements of test-piece  $\frac{1}{2}$  in. diameter, 2 ins. between gauge-marks:

Kind.	Ten- sile St'gth.	Elastic Limit.	El. in 2 ins., Per Ct.	Contr., Per Ct.	Kind.	T. S.	E. L.	El. in 2 ins., Per Ct.	Contr., Per Ct.
Aa	58,000	29,000 Y.P.	28	35	Da	80,000	45,000	23	40
Ba	75,000	37,500 Y.P.	18	30	Ea	80,000	50,000	25	45
Ca	80,000	40,000	22	35	Eb	80,000	45,000	25	45
Cb	75,000	37,500	23	35	Ec	80,000	45,000	24	40
Cc	70,000	35,000	24	30	Fd	95,000	65,000	21	50
Dd	90,000	55,000	20	45	Fe	90,000	60,000	22	50
De	85,000	50,000	22	45	Fa	85,000	55,000	24	45

The number and location of test specimens to be taken from a melt, blow, or forging depend upon its character and importance, and must therefore be regulated by individual cases. The yield-point (in steels A and B) shall be determined by observation of the drop of the beam or halt in the gauge of the testing-machine. The elastic limit shall be determined by means of an extensometer, and will be taken at that point where the proportionality changes.

*Bending Test.*—A specimen  $1 \times 1\frac{1}{2}$  ins. shall bend cold  $180^\circ$  without fracture on outside of bent portion, as follows. The test may be made by bending or by blows.

Around a diam. of ins.....	$\frac{1}{2}$	$1\frac{1}{2}$	$1\frac{1}{2}$	1	1	$\frac{1}{2}$	1
For kind .....	A	B	Cc	Cab	D	E	F

(4) **Tires.**—Physical requirements of test-piece  $\frac{1}{2}$  in. diam.: Tires for passenger engines: T. S., 100,000; El. in 2 ins., 12 per cent. Tires for freight engines and car wheels. T. S., 110,000; El., 10 per cent. Tires for switching engines: T. S., 120,000; El., 8 per cent.

*Drop-test.*—If a drop-test is called for, a selected tire shall be placed vertically under the drop on a foundation at least 10 tons in weight and subjected to successive blows from a tup weighing 2240 lbs. falling from increasing heights until the required deflection is obtained, without breaking or cracking. The minimum deflection must equal  $D^2 \div (40T^2 + 2D)$ , *D* being internal diameter and *T* thickness of tire at centre of tread.

(5) **Rails.**—One drop-test shall be made on a piece of rail not more than 6 ft. long, selected from every fifth blow of steel. The rail shall be placed head upwards on solid supports 3 ft. apart, which are part of, or firmly secured to, an anvil-block weighing at least 20,000 lbs., and subjected to the following impact tests.

Weight of rails, lbs. per yd.	45 to 55	55 to 65	65 to 75	75 to 85	85 to 100
Height of drop, ft.....	15	16	17	18	19

If any rail break when subjected to the drop-test, two additional tests will be made of other rails from the same blow of steel, and if either of these latter tests fail, all the rails of the blow which they represent will be rejected, but if both tests meet the requirements, all the rails of the blow will be accepted.

(6) **Splice-bars.**—Tensile strength of a specimen cut from the head of the bar, 54,000 to 64,000 lbs.; yield-point, 32,000 lbs. Elongation in 8 ins., not less than 25 per cent. A test specimen cut from the head of the bar shall bend  $180^\circ$  flat on itself without fracture on the outside of the bent portion. If preferred, the bending test may be made on an unpunched splice-bar, which shall be first flattened and then bent. One tensile test and one bending test to be made from each blow or melt of steel.

(7) **Structural Steel for Buildings.**

Class.	Rivet-steel.	Medium Steel.
Tensile strength, lbs. per sq. in. ....	50,000–60,000	60,000–70,000
Yield-point, not less than.....	$\frac{1}{2}$ T. S.	$\frac{1}{2}$ T. S.
Elongation in 8 ins., not less than.....	26 per cent.	22 per cent.

Modifications in elongation requirements: For each increase of  $\frac{1}{8}$  in. in thickness above  $\frac{3}{4}$  in., a deduction of 1 per cent in the specified elongation. For each decrease of  $\frac{1}{16}$  in. in thickness below  $\frac{5}{16}$  in., a deduction of  $2\frac{1}{2}$  per cent.

For pins the required elongation shall be 5 per cent less than that specified, as determined on a test specimen the centre of which shall be 1 in. from the surface.

*Bending Tests.*—Rivet-steel shall bend cold  $180^\circ$  flat on itself, and medium steel  $180^\circ$  around a diameter equal to the thickness of the specimen, without fracture on the outside of the bent portion.

One tensile and one bending-test specimen shall be taken from the finished material of each melt or blow.

### (8) Structural Material for Bridges and Ships.

Class.	Rivet-steel.	Soft Steel.	Medium Steel.
Tens. str., lbs. per sq. in..	50,000–60,000	52,000–62,000	60,000–70,000
Y. P., not less than. . . . .	$\frac{1}{2}$ T. S.	$\frac{1}{2}$ T. S.	$\frac{1}{2}$ T. S.
El. in 8 ins. not less than.	26 per cent.	25 per cent.	22 per cent.

Modifications in elongation: Same as in structural steel for buildings.

*Eyebars.*—Full-sized tests: T. S. not less than 55,000 lbs.; El.,  $12\frac{1}{2}$  per cent. in 15 ft. of the body.

*Bending Tests.*—Rivet and soft steel,  $180^\circ$  flat on itself, and medium steel  $180^\circ$  around a diameter equal to the thickness of the specimen, without fracture on the outside of the bent portion.

### (9) Boiler-plate and Rivet-steel.

Class.	Flange- or Boiler-steel.	Fire-box Steel.	Extra-soft Steel.
T. S., lbs per sq. in. . . . .	55,000–65,000	52,000–62,000	45,000–55,000
Y. P., not less than. . . . .	$\frac{1}{2}$ T. S.	$\frac{1}{2}$ T. S.	$\frac{1}{2}$ T. S.
El. in 8 ins. not less than	25 per cent.	26 per cent.	28 per cent.

Modifications in elongation requirements for thin and thick material same as in structural steel for buildings.

*Bending Tests.*—A specimen cut from the rolled material, both before and after quenching, shall bend cold  $180^\circ$  flat on itself without fracture on the outside of the bent portion. For the quenched test the specimen shall be heated to a light cherry-red as seen in the dark and quenched in water of a temperature between  $80^\circ$  and  $90^\circ$  F. Number of test-pieces: One tensile, one cold-bending, and one quenched-bending specimen will be furnished from each plate as it is rolled, and two specimens for each kind of test from each melt of rivet-rounds.

*Homogeneity Test for Fire-box Steel.*—This test is made on one of the broken tensile-test specimens, as follows:

A portion of the test-piece is nicked with a chisel, or grooved on a machine, transversely about a sixteenth of an inch deep, in three places about 2 in. apart. The first groove should be made on one side, 2 in. from the square end of the piece; the second, 2 in. from it on the opposite side; and the third, 2 in. from the last, and on the opposite side from it. The test-piece is then put in a vise, with the first groove about  $\frac{1}{4}$  in. above the jaws, care being taken to hold it firmly. The projecting end of the test-piece is then broken off by means of a hammer, a number of light blows being used, and the bending being away from the groove. The piece is broken at the other two grooves in the same way. The object of this treatment is to open and render visible to the eye any seams due to failure to weld up, or to foreign interposed matter, or cavities due to gas bubbles in the ingot. After rupture, one side of each fracture is examined, a pocket lens being used if necessary, and the length of the seams and cavities is determined. The sample shall not show any single seam or cavity more than  $\frac{1}{4}$  in. long in either of the three fractures.

### VARIOUS SPECIFICATIONS FOR STEEL.

**Structural Steel.**—There has been a change during the ten years from 1880 to 1890, in the opinions of engineers, as to the requirements in specifications for structural steel, in the direction of a preference for metal of low tensile strength and great ductility. The following specifications of different dates are given by A. E. Hunt and G. H. Clapp, *Trans. A. I. M. E.* 1890, xix, 926:

TENSION MEMBERS.	1879.	1881.	1882.	1885.	1887.	1888.
Elastic limit.....	50,000	40@45,000	40,000	40,000	40,000	38,000
Tensile strength.....	80,000	70@80,000	70,000	70,000	67@75,000	63@70,000
Elongation in 8 in.....	12%	18%	18%	18%	20%	22%
Reduction of area.....	20%	30%	45%	42%	42%	45%

F. H. Lewis (*Iron Age*, Nov. 3, 1892) says: Regarding steel to be used under the same conditions as wrought iron, that is, to be punched without reaming, there seems to be a decided opinion (and a growing one) among engineers, that it is not safe to use steel in this way, when the ultimate tensile strength is above 65,000 lbs. The reason for this is, not so much because there is any marked change in the material of this grade, but because all steel, especially Bessemer steel, has a tendency to segregations of carbon and phosphorus, producing places in the metal which are harder than they normally should be. As long as the percentages of carbon and phosphorus are kept low, the effect of these segregations is inconsiderable; but when these percentages are increased, the existence of these hard spots in the metal becomes more marked, and it is therefore less adapted to the treatment to which wrought iron is subjected.

There is a wide consensus of opinion that at an ultimate of 64,000 to 65,000 lbs. the percentages of carbon and phosphorus (which are the two hardening elements) reach a point where the steel has a tendency to become tender, and to crack when subjected to rough treatment.

A grade of steel, therefore, running in ultimate strength from 54,000 to 62,000 lbs., or in some cases to 64,000 lbs., is now generally considered a proper material for this class of work.

A. E. Hunt, *Trans. A. I. M. E.* 1892, says: Why should the tests for steel be so much more rigid than for iron destined for the same purpose? Some of the reasons are as follows: Experience shows that the acceptable qualities of one melt of steel offer no absolute guarantee that the next melt to it, even though made of the same stock, will be equally satisfactory.

Again, good wrought iron, in plates and angles, has a narrow range (from 25,000 to 27,000 lbs.) in elastic limit per square inch, and a tensile strength of from 46,000 to 52,000 lbs. per square inch; whereas for steel the range in elastic limit is from 27,000 to 80,000 lbs., and in tensile strength from 48,000 to 120,000 lbs. per square inch, with corresponding variations in ductility. Moreover, steel is much more susceptible than wrought iron to widely varying effects of treatment, by hardening, cold rolling, or overheating.

It is now almost universally recognized that soft steel, if properly made and of good quality, is for many purposes a safe and satisfactory substitute for wrought iron, being capable of standing the same shop-treatment as wrought iron. But the conviction is equally general, that poor steel, or an unsuitable grade of steel, is a very dangerous substitute for wrought iron even under the same unit strains.

For this reason it is advisable to make more rigid requirements in selecting material which may range between the brittleness of glass and a ductility greater than that of wrought iron.

**Boiler, Ship, and Tank Plates.**—Different specifications are the following (1889):

*United States Navy.*—Shell: Tensile strength, 58,000 to 67,000 lbs. per sq. in.; elongation, 22% in 8-in. transverse section, 25% in 8-in. longitudinal section.

Flange: Tensile strength, 50,000 to 58,000 lbs.; elongation, 26% in 8 inches.

Chemical requirements: P. not over .035%; S. not over .040%.

Cold-bending test: Specimen to stand being bent flat on itself.

Quenching test: Steel heated to cherry-red, plunged in water 82° F., and to be bent around curve  $1\frac{1}{2}$  times thickness of the plate.

*British Admiralty.*—Tensile strength, 58,240 to 67,200 lbs.; elongation in 8 in., 20%; same cold-bending and quenching tests as U. S. Navy.

*American Boiler-makers' Association.*—Tensile strength, 55,000 to 65,000 lbs.; elongation in 8 in., 20% for plates  $\frac{3}{8}$  in. thick and under; 22% for plates  $\frac{3}{8}$  in. to  $\frac{3}{4}$  in.; 25% for plates  $\frac{3}{4}$  in. and over.

**Cold-bending test:** For plates  $\frac{1}{2}$  in. thick and under, specimen must bend back on itself without fracture; for plates over  $\frac{1}{2}$  in. thick, specimen must withstand bending  $180^\circ$  around a mandril  $1\frac{1}{2}$  times the thickness of the plate.

**Chemical requirements:** P not over .040%; S not over .030%.

*American Shipmasters' Association.*—Tensile strength, 62,000 to 72,000 lbs.; elongation, 16% on pieces 9 in. long.

Strips cut from plates, heated to a low red and cooled in water the temperature of which is  $82^\circ$  F., to undergo without crack or fracture being doubled over a curve the diameter of which does not exceed three times the thickness of the piece tested.

**Steel Plate Used in the Construction of Cars.** (Penna. R. R., 1899.)\*—The material desired has the following composition: C, 0.12; Mn, 0.35; Si, 0.05; P, not above 0.04; S, not above 0.03. It will be rejected if P exceeds 0.05, or if it shows a tensile strength below 52,000 or above 62,000 lbs. per sq. in., or if the percentage of elongation in 8 ins. is less than the quotient of  $1,500,000 \div$  the tensile strength.

**Steel Billets for Main and Parallel Rods.** (Penna. R. R., 1893.)—One billet from each lot of 25 billets or smaller shipment of steel for main or parallel rods for locomotives will have a piece drawn from it under the hammer and a test-section will be turned down on this piece to  $\frac{5}{8}$  in. in diameter and 2 in. long. Such test-piece should show a tensile strength of 85,000 lbs. and an elongation of 15%.

No lot will be acceptable if the test shows less than 80,000 lbs. tensile strength or 12% elongation in 2 in.

**Bar Spring Steel.** (Penna. R. R., 1901.)—Bars which vary more than 0.01 in. in thickness, or more than 0.02 in. in width, from the size ordered, or which break where they are not nicked, or which, when properly nicked and held, fail to break square across where they are nicked, will be returned. The metal desired has the following composition: Carbon, 1.00%; manganese, 0.25%; phosphorus, not over 0.03%; silicon, not over 0.15%; sulphur, not over 0.03%; copper, not over 0.03%.

Shipments will not be accepted which show on analysis less than 0.90% or over 1.10% of carbon, or over 0.50% of manganese, 0.05% of phosphorus, 0.25% of silicon, 0.05% of sulphur, and 0.05% of copper.

**Steel for Crank-pins.** (Penna. R. R., 1897.)—The metal desired has the following composition: C, 0.45; Mn, not above 0.60; Si, not above 0.05; P, not above 0.03; S, not above 0.04. The tensile strength should be 85,000 lbs. per sq. in., and the elongation 18% in 8 in. Borings for analysis will be taken from one axle out of a lot of 51. They will be drilled parallel with the axis with a  $\frac{5}{8}$ -in. drill, starting from a punch-mark located on the end, 40 per cent of the distance from the centre to the circumference. Two pieces from this pin will also be tested physically. The lot will be rejected if the P is above 0.05%, or if either test-piece shows less than 80,000 lbs. or above 95,000 lbs. T. S., less than 12% elongation, or if the T. S. of the two test-pieces differs more than 5,000 lbs. or the elongation more than 5%.

Dr. Chas. B. Dudley, chemist of the P. R. R. (Trans. A. I. M. E. 1892), referring to tests of crank-pins, says: In testing a recent shipment, the piece from one side of the pin showed 88,000 lbs. strength and 22% elongation, and the piece from the opposite side showed 106,000 lbs. strength and 14% elongation. Each piece was above the specified strength and ductility, but the lack of uniformity between the two sides of the pin was so marked that it was finally determined not to put the lot of 50 pins in use. To guard against trouble of this sort in future, the specifications are to be amended to require that the difference in ultimate strength of the two specimens shall not be more than 3000 lbs.

**Steel Rivets.** (H. C. Torrance, Amer. Boiler Mfrs. Assn., 1890.)—The Government requirements for the rivets used in boilers of the cruisers built in 1890 are: For longitudinal seams, 58,000 to 67,000 lbs. tensile strength; elongation, not less than 26% in 8 in., and all others a tensile strength of 50,000 to 58,000 lbs., with an elongation of not less than 30%. They shall be capable of being flattened out cold under the hammer to a thickness of one half the diameter, and of being flattened out hot to a thickness of one third

\* The Penna. R. R. specifications of the several dates given are still in force, July, 1902.

the diameter without showing cracks or flaws. The steel must not contain more than .035 of 1% of phosphorus, nor more than .04 of 1% of sulphur.

A lot of 20 successive tests of rivet steel of the low tensile strength quality and 12 tests of the higher tensile strength gave the following results :

	Low Steel.	Higher.
Tensile strength, lbs. per sq. in. . . . .	51,230 to 51,100	59,100 to 61,850
Elastic limit, lbs. per sq. in. . . . .	31,050 to 33,190	32,080 to 33,070
Elongation in 8 in., per cent. . . . .	30.5 to 35.25	28.5 to 31.75
Carbon, per cent. . . . .	.11 to .14	.16 to .18
Phosphorus . . . . .	.027 to .029	.03
Sulphur. . . . .	.033 to .035	.033 to .035

The safest steel rivets are those of the lowest tensile strength, since they are the least liable to become hardened and fracture by hammering, or to break from repeated concussive and vibratory strains to which they are subjected in practice. For calculations of the strength of riveted joints the tensile strength may be taken as the average of the figures above given, or 52,665 lbs., and the shearing strength at 45,000 lbs. per sq. in.

### MISCELLANEOUS NOTES ON STEEL.

**May Carbon be Burned Out of Steel?**—Experiments made at the Laboratory of the Penna. Railroad Co. (Specifications for Springs, 1888) with the steel of spiral springs, show that the place from which the borings are taken for analysis has a very important influence on the amount of carbon found. If the sample is a piece of the round bar, and the borings are taken from the end of this piece, the carbon is always higher than if the borings are taken from the side of the piece. It is common to find a difference of 0.10% between the centre and side of the bar, and in some cases the difference is as high as 0.23%. Furthermore, experiments made with samples taken from the drawn out end of the bar show, usually, less carbon than samples taken from the round part of the bar, even though the borings may be taken out of the side in both cases.

Apparently during the process of reducing the metal from the ingots to the round bar, with successive heatings, the carbon in the outside of the bar is burned out.

**“Recalescence” of Steel.**—If we heat a bar of copper by a flame of constant strength, and note carefully the interval of time occupied in passing from each degree to the next higher degree, we find that these intervals increase regularly, i. e., that the bar heats more and more slowly, as its temperature approaches that of the flame. If we substitute a bar of steel for one of copper, we find that these intervals increase regularly up to a certain point, when the rise of temperature is suddenly and in most cases greatly retarded or even completely arrested. After this the regular rise of temperature is resumed, though other like retardations may recur as the temperature rises farther. So if we cool a bar of steel slowly the fall of temperature is greatly retarded when it reaches a certain point in dull redness. If the steel contains much carbon, and if certain favoring conditions be maintained, the temperature, after descending regularly, suddenly rises spontaneously very abruptly, remains stationary a while, and then redescends. This spontaneous reheating is known as “recalescence.”

These retardations indicate that some change which absorbs or evolves heat occurs within the metal. A retardation while the temperature is rising points to a change which absorbs heat; a retardation during cooling points to some change which evolves heat. (Henry M. Howe, on “Heat Treatment of Steel,” Trans. A. I. M. E., vol. xxii.)

**Effect of Nicking a Steel Bar.**—The statement is sometimes made that, owing to the homogeneity of steel, a bar with a surface crack or nick in one of its edges is liable to fail by the gradual spreading of the nick, and thus break under a very much smaller load than a sound bar. With iron it is contended this does not occur, as this metal has a fibrous structure. Sir Benjamin Baker has, however, shown that this theory, at least so far as statical stress is concerned, is opposed to the facts, as he purposely made nicks in specimens of the mild steel used at the Forth Bridge, but found that the tensile strength of the whole was thus reduced by only about one ton per square inch of section. In an experiment by the Union Bridge Company a full-sized steel counter-bar, with a screw-turned buckle connection, was tested under a heavy statical stress, and at the same time a weight weighing 1040 lbs. was allowed to drop on it from various heights. The bar was first broken by ordinary statical strain, and showed a breaking stress of

66,800 lbs. per square inch. The longer of the broken parts was then placed in the machine and put under the following loads, whilst a weight, as already mentioned, was dropped on it from various heights at a distance of five feet from the sleeve-nut of the turn-buckle, as shown below:

Stress in pounds per sq. in. ....	50,000	55,000	60,000	63,000	65,000
	ft. in.				
Height of fall.....	2 1	2 6	3 0	4 0	5 0

The weight was then shifted so as to fall directly on the sleeve-nut, and the test proceeded as follows:

Stress on specimen in lbs. per square inch.....	65,350	65,350	68,800
Height of fall, feet.....	3	6	6

It will be seen that under this trial the bar carried more than when originally tested statically, showing that the nicking of the bar by screwing had not appreciably weakened its power of resisting shocks.—*Eng'g News*.

**Electric Conductivity of Steel.**—Louis Campredon reports in *Le Genie Civil* [prior to 1895] the results of experiments on the electric resistance of steel wires of different composition, ranging from 0.09 to 0.14 C; 0.21 to 0.54 Mn; Si, S, and P low. The figures show that the purer and softer the steel the better is its electric conductivity, and, furthermore, that manganese is the element which most influences the conductivity. The results may be expressed by the formula  $R = 5.2 + 6.2S \pm 0.3$ ; in which  $R$  = relative resistance, copper being taken as 1, and  $S$  = the sum of the percentages of C, P, S, Si, and Mn. The conclusions are confirmed by J. A. Capp, in 1903, *Trans. A. I. M. E.*, vol. xxxiv, who made forty-five experiments on steel of a wide range of composition. His results may be expressed by the formula  $R = 5.5 + 4S \pm 1$ . High manganese increases the resistance at an increasing rate. Mr. Capp proposes the following specification for steel to make a satisfactory third rail, having a resistance eight times that of copper: C, 0.15; Mn, 0.30; P, 0.06; S, 0.06; Si, 0.05; none of these figures to be exceeded.

**Specific Gravity of Soft Steel.** (W. Kent, *Trans. A. I. M. E.*, xiv, 585.)—Five specimens of boiler-plate of C. 0.14, P. 0.03 gave an average sp. gr. of 7.932, maximum variation 0.008. The pieces were first planed to remove all possible scale indentations, then filed smooth, then cleaned in dilute sulphuric acid, and then boiled in distilled water, to remove all traces of air from the surface.

The figures of specific gravity thus obtained by careful experiment on bright, smooth pieces of steel are, however, too high for use in determining the weights of rolled plates for commercial purposes. The actual average thickness of these plates is always a little less than is shown by the calipers, on account of the oxide of iron on the surface, and because the surface is not perfectly smooth and regular. A number of experiments on commercial plates, and comparison of other authorities, led to the figure 7.854 as the average specific gravity of open-hearth boiler-plate steel. This figure is easily remembered as being the same figure with change of position of the decimal point (.7854) which expresses the relation of the area of a circle to that of its circumscribed square. Taking the weight of a cubic foot of water at 62° F. as 62.36 lbs. (average of several authorities), this figure gives 489.775 lbs. as the weight of a cubic foot of steel, or the even figure, 490 lbs., may be taken as a convenient figure, and accurate within the limits of the error of observation.

A common method of approximating the weight of iron plates is to consider them to weigh 40 lbs. per square foot one inch thick. Taking this weight and adding 2% gives almost exactly the weight of steel boiler-plate given above ( $40 \times 12 \times 1.02 = 489.6$  lbs. per cubic foot).

**Occasional Failures of Bessemer Steel.**—G. H. Clapp and A. E. Hunt, in their paper on "The Inspection of Materials of Construction in

the United States" (Trans. A. I. M. E., vol. xix), say: Numerous instances could be cited to show the unreliability of Bessemer steel for structural purposes. One of the most marked, however, was the following: A 12-in. I-beam weighing 30 lbs. to the foot, 20 feet long, on being unloaded from a car broke in two about 6 feet from one end.

The analyses and tensile tests made do not show any cause for the failure.

The cold and quench bending tests of both the original  $\frac{3}{4}$ -in. round test-pieces, and of pieces cut from the finished material, gave satisfactory results; the cold-bending tests closing down on themselves without sign of fracture.

Numerous other cases of angles and plates that were so hard in places as to break off short in punching, or, what was worse, to break the punches, have come under our observation, and although makers of Bessemer steel claim that this is just as likely to occur in open-hearth as in Bessemer steel, we have as yet never seen an instance of failure of this kind in open-hearth steel having a composition such as C 0.25%, Mn 0.70%, P 0.80%.

J. W. Wailes, in a paper read before the Chemical Section of the British Association for the Advancement of Science, in speaking of mysterious failures of steel, states that investigation shows that "these failures occur in steel of one class, viz., soft steel made by the Bessemer process."

**Segregation in Steel Ingots.** (A. Pourcel, Trans. A. I. M. E. 1893.)—H. M. Howe, in his "Metallurgy of Steel," gives a *résumé* of observations with the results of numerous analyses, bearing upon the phenomena of segregation.

In 1881 Mr. Stubbs, of Manchester, showed the heterogeneous results of analyses made upon different parts of an ingot of large section.

A test-piece taken 24 inches from the head of the ingot 7.5 feet in length gave by analysis very different results from those of a test-piece taken 30 inches from the bottom.

	C.	Mn.	Si.	S.	P.
Top. ....	0.92	0.535	0.043	0.161	0.261
Bottom.....	0.37	0.498	0.006	0.025	0.096

Windsor Richards says he had often observed in test-pieces taken from different points of one plate variations of 0.05% of carbon. Segregation is specially pronounced in an ingot in its central portion, and around the space of the piping.

It is most observable in large ingots, but in blocks of smaller weight and limited dimensions, subjected to the influence of solidification as rapid as casting within thick walls will permit, it may still be observed distinctly. An ingot of Martin steel, weighing about 1000 lbs., and having a height of 1.10 feet and a section of 10.24 inches square, gave the following:

1. Upper section:	C.	S.	P.	Mn.
Border .....	0.330	0.040	0.033	0.420
Centre.....	0.530	0.077	0.057	0.430
2. Lower section:	C.	S.	P.	Mn.
Border .....	0.280	0.029	0.016	0.390
Centre.....	0.290	0.030	0.038	0.390
3. Middle section:	C.	S.	P.	Mn.
Border .....	0.320	0.025	0.025	0.400
Centre.....	0.320	0.048	0.048	0.400

Segregation is less marked in ingots of extra-soft metal cast in cast-iron moulds of considerable thickness. It is, however, still important, and explains the difference often shown by the results of tests on pieces taken from different portions of a plate. Two samples, taken from the sound part of a flat ingot, one on the outside and the other in the centre, 7.9 inches from the upper edge, gave:

	C.	S.	P.	Mn.
Centre.....	0.14	0.053	0.072	0.576
Exterior.....	0.11	0.036	0.027	0.610

Manganese is the element most uniformly disseminated in hard or soft steel.

For cannon of large calibre, if we reject, in addition to the part cast in sand and called the *masselotte* (sinking-head), one third of the upper part of the ingot, we can obtain a tube practically homogeneous in composition, because the central part is naturally removed by the boring of the tube. With extra-soft steels, destined for ship- or boiler-plates, the solution for practically perfect homogeneity lies in the obtaining of a metal more closely deserving its name of extra-soft metal.

The injurious consequences of segregation must be suppressed by reducing, as far as possible, the elements subject to liquation.

**Earliest Uses of Steel for Structural Purposes.** (G. G. Mehrrens, Trans. A. S. C. E. 1893).—The Pennsylvania Railroad Company first introduced Bessemer steel in America in locomotive boilers in the year 1863, but the steel was too hard and brittle for such use. The first plates made for steel boilers had a tenacity of 85,000 to 92,000 lbs. and an elongation of but 7% to 10%. The results were not favorable, and the steel works were soon forced to offer a material of less tenacity and more ductility. The requirements were therefore reduced to a tenacity of 78,000 lbs. or less, and the elongation was increased to 15% or more. The use of Bessemer steel in bridge-building was tried first on the Dutch State railways in 1863-64, then in England and Austria. The first use of cast steel for bridges was in America, for the St. Louis Arch Bridge and for the wire of the East River Bridge. Before 1880 the Glasgow and Plattsmouth bridges over the Missouri River were also built of ingot metal. Steel eyebars were applied for the first time in the Glasgow Bridge. Since 1880 the introduction of mild steel in all kinds of engineering structures has steadily increased.

Messrs. Joseph Adamson & Co., of Hyde, England, in a letter to the author say: "The first steel for boiler purposes was used for a locomotive firebox sent to Africa in 1853. The first steel steamships were built in Liverpool for 'blockade-running' during the American Civil War about 1862, and at least 5000 tons of Bessemer steel plates were rolled at Penistone by Benson, Adamson & Garnett for this purpose. The first Bessemer steel boilers were made in this neighborhood in 1858. Drilling the rivet-holes was adopted in 1859. Some of these boilers built in 1862 worked 29 years night and day. We have lost trace of these boilers now, but we know that after working this length of time they were found good enough to be worth resetting and were set to work again for a time. Between 1870 and 1880 about 2000 steel land boilers were working in this country. The pressures ranged up to 150 lbs."

## STEEL CASTINGS.

(E. S. Cramp, Engineering Congress, Dept. of Marine Eng'g, Chicago, 1893.)

In 1891 American steel-founders had successfully produced a considerable variety of heavy and difficult castings, of which the following are the most noteworthy specimens:

Bed-plates up to 24,000 lbs.; stern-posts up to 54,000 lbs.; stems up to 21,000 lbs.; hydraulic cylinders up to 11,000 lbs.; shaft-struts up to 32,000 lbs.; hawse-pipes up to 7500 lbs.; stern-pipes up to 8000 lbs.

The percentage of success in these classes of castings since 1890 has ranged from 65% in the more difficult forms to 90% in the simpler ones; the tensile strength has been from 62,000 to 78,000 lbs., elongation from 15% to 25%. The best performance recorded is that of a guide, cast in January, 1893, which developed 84,000 lbs. tensile strength and 15.6% elongation.

The first steel castings of which anything is generally known were crossing-frogs made for the Philadelphia & Reading R. R. in July, 1867, by the William Butcher Steel Works, now the Midvale Steel Co. The moulds were made of a mixture of ground fire-brick, black-lead crucible-pots ground fine, and fire-clay, and washed with a black-lead wash. The steel was melted in crucibles, and was about as hard as tool steel. The surface of these castings was very smooth, but the interior was very much honey-combed. This was before the days when the use of silicon was known for solidifying steel. The sponginess, which was almost universal, was a great obstacle to their general adoption.

The next step was to leave the ground pots out of the moulding mixture and to wash the mould with finely ground fire-brick. This was a great improvement, especially in very heavy castings; but this mixture still clung so strongly to the casting that only comparatively simple shapes could be made with certainty. A mould made of such a mixture became almost as hard as fire-brick, and was such an obstacle to the proper shrinkage of castings, that, when at all complicated in shape, they had so great a tendency to crack as to make their successful manufacture almost impossible. By this time the use of silicon had been discovered, and the only obstacle in the way of making good castings was a suitable moulding mixture. This was ultimately found in mixtures having the various kinds of silica sand as the principal constituent.

One of the most fertile sources of defects in castings is a bad design. Very intricate shapes can be cast successfully if they are so designed as to

cool uniformly. Mr. Cramp says while he is not yet prepared to state that anything that can be cast successfully in iron can be cast in steel, indications seem to point that way in all cases where it is possible to put on suitable sinking-heads for feeding the casting.

H. L. Gantt (Trans. A. S. M. E., xii. 710) says: Steel castings not only shrink much more than iron ones, but with less regularity. The amount of shrinkage varies with the composition and the heat of the metal; the hotter the metal the greater the shrinkage; and, as we get smoother castings from hot metal, it is better to make allowance for large shrinkage and pour the metal as hot as possible. Allow  $\frac{3}{16}$  or  $\frac{1}{4}$  in. per ft. in length for shrinkage, and  $\frac{1}{4}$  in. for finish on machined surfaces, except such as are cast "up." Cope surfaces which are to be machined should, in large or hard castings, have an allowance of from  $\frac{3}{8}$  to  $\frac{1}{2}$  in. for finish, as a large mass of metal slowly rising in a mould is apt to become crusty on the surface, and such a crust is sure to be full of imperfections. On small, soft castings  $\frac{1}{8}$  in. on drag side and  $\frac{1}{4}$  in. on cope side will be sufficient. No core should have less than  $\frac{1}{4}$  in. finish on a side and very large ones should have as much as  $\frac{1}{2}$  in. on a side. Blow-holes can be entirely prevented in castings by the addition of manganese and silicon in sufficient quantities; but both of these cause brittleness, and it is the object of the conscientious steel-maker to put no more manganese and silicon in his steel than is just sufficient to make it solid. The best results are arrived at when all portions of the castings are of a uniform thickness, or very nearly so.

The following table will illustrate the effect of annealing on tensile strength and elongation of steel castings:

Carbon.	Unannealed.		Annealed.	
	Tensile Strength.	Elongation.	Tensile Strength.	Elongation.
.23%	68,738	22.40%	67,210	31.40%
.37	85,540	8.20	82,228	21.80
.53	90,121	2.35	106,415	9.80

The proper annealing of large castings takes nearly a week.

The proper steel for roll pinions, hammer dies, etc., seems to be that containing about .60% of carbon. Such castings, properly annealed, have worn well and seldom broken. Miscellaneous gearing should contain carbon .40% to .60%, gears larger in diameter being softest. General machinery castings should, as a rule, contain less than .40% of carbon, those exposed to great shocks containing as low as .20% of carbon. Such castings will give a tensile strength of from 60,000 to 80,000 lbs. per sq. in. and at least 15% extension in a 2 in. long specimen. Machinery and hull castings for war-vessels for the United States Navy, as well as carriages for naval guns, contain from .20% to .30% of carbon.

The following is a partial list of castings in which steel seems to be rapidly taking the place of iron: Hydraulic cylinders, crossheads and pistons for large engines, roughing rolls, rolling-mill spindles, coupling-boxes, roll pinions, gearing, hammer-heads and dies, riveter stakes, castings for ships, car-couplers, etc.

For description of methods of manufacture of steel castings by the Bessemer, open-hearth, and crucible processes, see paper by P. G. Salom, Trans. A. I. M. E. xiv, 118.

Specifications for steel castings issued by the U. S. Navy Department, 1889 (abridged): Steel for castings must be made by either the open-hearth or the crucible process, and must not show more than .06% of phosphorus. All castings must be annealed, unless otherwise directed. The tensile strength of steel castings shall be at least 60,000 lbs., with an elongation of at least 15% in 8 in. for all castings for moving parts of the machinery, and at least 10% in 8 in. for other castings. Bars 1 in. sq. shall be capable of bending cold, without fracture, through an angle of 90°, over a radius not greater than  $1\frac{1}{2}$  in. All castings must be sound, free from injurious roughness, sponginess, pitting, shrinkage, or other cracks, cavities, etc.

Pennsylvania Railroad specifications, 1888: Steel castings should have a tensile strength of 70,000 lbs. per sq. in. and an elongation of 15% in section originally 2 in. long. Steel castings will not be accepted if tensile strength

falls below 60,000 lbs., nor if the elongation is less than 12%, nor if castings have blow-holes and shrinkage cracks. Castings weighing 80 lbs. or more must have cast with them a strip to be used as a test-piece. The dimensions of this strip must be  $\frac{3}{4}$  in. sq. by 12 in. long.

### MANGANESE, NICKEL, AND OTHER "ALLOY" STEELS.

**Manganese Steel.** (H. M. Howe, Trans. A. S. M. E., vol. xii.)—Manganese steel is an alloy of iron and manganese, incidentally, and probably unavoidably, containing a considerable proportion of carbon.

The effect of small proportions of manganese on the hardness, strength, and ductility of iron is probably slight. The point at which manganese begins to have a predominant effect is not known: it may be somewhere about 2.5%. As the proportion of manganese rises above 2.5% the strength and ductility diminish, while the hardness increases. This effect reaches a maximum with somewhere about 6% of manganese. When the proportion of this element rises beyond 6% the strength and ductility both increase, while the hardness diminishes slightly, the maximum of both strength and ductility being reached with about 14% of manganese. With this proportion the metal is still so hard that it is very difficult to cut it with steel tools. As the proportion of manganese rises above 15% the ductility falls off abruptly, the strength remaining nearly constant till the manganese passes 18%, when it in turn diminishes suddenly.

Steel containing from 4% to 6.5% of manganese, even if it have but 0.37% of carbon, is reported to be so extremely brittle that it can be powdered under a hand-hammer when cold; yet it is ductile when hot.

Manganese steel is very free from blow-holes; it welds with great difficulty; its toughness is increased by quenching from a yellow heat; its electric resistance is enormous, and very constant with changing temperature; it is low in thermal conductivity. Its remarkable combination of great hardness, which cannot be materially lessened by annealing, and great tensile strength, with astonishing toughness and ductility, at once creates and limits its usefulness. The fact that manganese steel cannot be softened, that it ever remains so hard that it can be machined only with great difficulty, sets up a barrier to its usefulness.

The following comparative results of abrasion tests of manganese and other steel were reported by T. T. Morrell:

#### ABRASION BY PRESSURE AGAINST A REVOLVING HARDENED-STEEL SHAFT.

Loss of weight of manganese steel.....	1.0
“ blue-tempered hard tool steel.....	0.4
“ annealed hard tool steel. ....	7.5
“ hardened Otis boiler-plate steel.....	7.0
“ annealed “ “ .....	14.0

#### ABRASION BY AN EMERY-WHEEL.

Loss of weight of hard manganese-steel wheels.....	1.00
“ softer “ “ .....	1.19
“ hardest carbon-steel wheels.....	1.23
“ soft “ “ .....	2.85

The hardness of manganese steel seems to be of an anomalous kind. The alloy is hard, but under some conditions not rigid. It is very hard in its resistance to abrasion; it is not always hard in its resistance to impact.

Manganese steel forges readily at a yellow heat, though at a bright white heat it crumbles under the hammer. But it offers greater resistance to deformation, i.e., it is harder when hot, than carbon steel.

The most important single use for manganese-steel is for the pins which hold the buckets of elevator dredges. Here abrasion chiefly is to be resisted.

Another important use is for the links of common chain-elevators.

As a material for stamp-shoes, for horse-shoes, for the knuckles of an automatic car-coupler, manganese steel has not met expectations.

Manganese steel has been regularly adopted for the blades of the Cyclone pulverizer. Some manganese-steel wheels are reported to have run over 300,000 miles each without turning, on a New England railroad.

**Nickel Steel.**—The remarkable tensile strength and ductility of nickel steel, as shown by the test-bars and the behavior of nickel-steel armor-plate under shot tests, are witness of the valuable qualities conferred upon steel by the addition of a few per cent of nickel.

The following tests were made on nickel steels by Mr. Maunsel White of the Bethlehem Iron Company (*Eng. & M. Jour.*, Sept. 16, 1893.):

	Specimen from—	Diam., in.	Length, in.	Tensile Str'ngth, lbs. per sq. in.	Elastic Limit, lbs. per sq. in.	Elongation, %	Reduction of Area, %	
3¼% nickel steel.	Forged bars.*	.625	4	276,800	.....	2.75	.....	Special treatment. Annealed.
		"	"	246,595	.....	4.25	6.0	
		"	"	105,300	.....	19.25	55.0	
	1¼-in. round rolled bar.†	.564	4	142,800	74,000	13.0	28.2	
		"	"	143,200	74,000	12.32	27.6	
		"	"	117,600	64,000	17.0	46.0	
		"	"	119,200	65,000	16.66	42.1	
		"	"	91,600	51,000	22.25	53.2

§ Rolled down from 14-in. ingot to 1-in. round, and turned to size.

Nickel steel has shown itself to be possessed of some exceedingly valuable properties; these are, resistance to cracking, high elastic limit, and homogeneity. Resistance to cracking, a property to which the name of non fissibility has been given, is shown more remarkably as the percentage of nickel increases. Bars of 27% nickel illustrate this property. A 1¼-in. square bar was nicked ¼ in. deep and bent double on itself without further fracture than the splintering off, as it were, of the nicked portion. Sudden failure or rupture of this steel would be impossible; it seems to possess the toughness of rawhide with the strength of steel. With this percentage of nickel the steel is practically non-corrodible and non-magnetic. The resistance to cracking shown by the lower percentages of nickel is best illustrated in the many trials of nickel-steel armor.

The elastic limit rises in a very marked degree with the addition of about 3% of nickel, the other physical properties of the steel remaining unchanged or perhaps slightly increased.

In such places (shafts, axles, etc.) where failure is the result of the fatigue of the metal this higher elastic limit of nickel steel will tend to prolong indefinitely the life of the piece, and at the same time, through its superior toughness, offer greater resistance to the sudden strains of shock.

Howe states that the hardness of nickel steel depends on the proportion of nickel and carbon jointly, nickel up to a certain percentage increasing the hardness, beyond this lessening it. Thus while steel with 2% of nickel and 0.90% of carbon cannot be machined, with less than 5% nickel it can be worked cold readily, provided the proportion of carbon be low. As the proportion of nickel rises higher, cold-working becomes less easy. It forges easily whether it contain much or little nickel.

The presence of manganese in nickel steel is most important, as it appears that without the aid of manganese in proper proportions, the conditions of treatment would not be successful.

**Tests of Nickel Steel.**—Two heats of open-hearth steel were made by the Cleveland Rolling Mill Co., one ordinary steel made with 9000 lbs. each scrap and pig, and 165 lbs. ferro-manganese, the other the same with the addition of 3%, or 540 lbs. of nickel. Tests of six plates rolled from each heat., 0.24 to 0.3 in. thick, gave results as follows:

Ordinary steel, T. S. 52,500 to 56,500; E. L. 32,800 to 37,900; elong. 26 to 32%.  
 Nickel steel, " 63,370 to 67,100; " 47,100 to 48,200; " 23¼ to 26%.

The nickel steel averages 31% higher in elastic limit, 20% higher in ultimate tensile strength, with but slight reduction in ductility. (*Eng. & M. Jour.*, Feb. 25, 1893.)

**Aluminum Steel.**—R. A. Hadfield (*Trans. A. I. M. E.* 1890) says: Aluminum appears to be of service as an addition to baths of molten iron or steel unduly saturated with oxides, and this in properly regulated steel manufacture should not often occur. Speaking generally, its rôle appears to be similar to that of silicon, though acting more powerfully. The statement that aluminum lowers the melting-point of iron seems to have no foundation in fact. If any increase of heat or fluidity takes place by the addition of small amounts of aluminum, it may be due to evolution of heat, owing to oxidation of the aluminum, as the calorific value of this metal is very high—in fact, higher than silicon. According to Berthollet, the conversion of aluminum to  $Al_2O_3$  equals 7900 cal.; silicon to  $SiO_2$  is stated as 7800.

The action of aluminum may be classed along with that of silicon, sulphur, phosphorus, arsenic, and copper, as giving no increase of hardness to iron, in contradistinction to carbon, manganese, chromium, tungsten, and nickel. Therefore, whilst for some special purposes aluminum may be employed in the manufacture of iron, at any rate with our present knowledge of its properties, this use cannot be large, especially when taking into consideration the fact of its comparatively high price. Its special advantage seems to be that it combines in itself the advantages of both silicon and manganese; but so long as alloys containing these metals are so cheap and aluminum dear, its extensive use seems hardly probable.

J. E. Stead, in discussion of Mr. Hadfield's paper, said: Every one of our trials has indicated that aluminum can kill the most fiery steel, providing, of course, that it is added in sufficient quantity to combine with all the oxygen which the steel contains. The metal will then be absolutely dead, and will pour like dead-melted silicon steel. If the aluminum is added as metallic aluminum, and not as a compound, and if the addition is made just before the steel is cast, 1/10% is ample to obtain perfect solidity in the steel.

**Chrome Steel.** (F. L. Garrison, *Jour. F. I.*, Sept. 1891.)—Chromium increases the hardness of iron, perhaps also the tensile strength and elastic limit, but it lessens its weldability.

Ferro chrome, according to Berthier, is made by strongly heating the mixed oxides of iron and chromium in brasqued crucibles, adding powdered charcoal if the oxide of chromium is in excess, and fluxes to scorify the earthy matter and prevent oxidation. Chromium does not appear to give steel the power of becoming harder when quenched or chilled. Howe states that chrome steels forge more readily than tungsten steels, and when not containing over 0.5 of chromium nearly as well as ordinary carbon steels of like percentage of carbon. On the whole the status of chrome steel is not satisfactory. There are other steel alloys coming into use, which are so much better, that it would seem to be only a question of time when it will drop entirely out of the race. Howe states that many experienced chemists have found no chromium, or but the merest traces, in chrome steel sold in the markets.

J. W. Langley (*Trans. A. S. C. E.* 1892) says: Chromium, like manganese, is a true hardener of iron even in the absence of carbon. The addition of 1% or 2% of chromium to a carbon steel will make a metal which gets excessively hard. Hitherto its principal employment has been in the production of chilled shot and shell. Powerful molecular stresses result during cooling, and the shells frequently break spontaneously months after they are made.

**Tungsten Steel—Mushet Steel.** (J. B. Nau, *Iron Age*, Feb. 11, 1892.)—By incorporating simultaneously carbon and tungsten in iron, it is possible to obtain a much harder steel than with carbon alone, without danger of an extraordinary brittleness in the cold metal or an increased difficulty in the working of the heated metal.

When a special grade of hardness is required, it is frequently the custom to use a high tungsten steel, known in England as special steel. A specimen from Sheffield, used for chisels, contained 9.3% of tungsten, 0.7% of silver, and 0.6% of carbon. This steel, though used with advantage in its untempered state to turn chilled rolls, was not brittle; nevertheless it was hard enough to scratch glass.

A sample of Mushet's special steel contained 8.3% of tungsten and 1.73% of manganese. The hardness of tungsten steel cannot be increased by the ordinary process of hardening.

The only operation that it can be submitted to when cold is grinding. It has to be given its final shape through hammering at a red heat, and even

then, when the percentage of tungsten is high, it has to be treated very carefully; and in order to avoid breaking it, not only is it necessary to reheat it several times while it is being hammered, but when the tool has acquired the desired shape hammering must still be continued gently and with numerous blows until it becomes nearly cold. Then only can it be cooled entirely.

Tungsten is not only employed to produce steel of an extraordinary hardness, but more especially to obtain a steel which, with a moderate hardness, allies great toughness, resistance, and ductility. Steel from Assailly, used for this purpose, contained carbon, 0.52%; silicon, 0.04%; tungsten, 0.3%; phosphorus, 0.04%; sulphur, 0.005%.

Mechanical tests made by Styffe gave the following results :

Breaking load per square inch of original area, pounds..	172,424
Reduction of area, per cent .....	0.54
Average elongation after fracture, per cent .....	13

According to analyses made by the Duc de Luynes of ten specimens of the celebrated Oriental damasked steel, eight contained tungsten, two of them in notable quantities (0.518% to 1%), while in all of the samples analyzed nickel was discovered ranging from traces to nearly 4%.

Stein & Schwartz of Philadelphia, in a circular say: It is stated that tungsten steel is suitable for the manufacture of steel magnets, since it retains its magnetism longer than ordinary steel. Mr. Kniesche has made tungsten up to 98% fine a specialty. Dr. Heppe, of Leipzig, has written a number of articles in German publications on the subject. The following instructions are given concerning the use of tungsten: In order to produce cast iron possessing great hardness an addition of one half to one and one half of tungsten is all that is needed. For bar iron it must be carried up to 1% to 2%, but should not exceed 2½%. For puddled steel the range is larger, but an addition beyond 3½% only increases the hardness, so that it is brought up to 1½% only for special tools, coinage dies, drills, etc. For tires 2½% to 5% have proved best, and for axles ½ to 1½%. Cast steel to which tungsten has been added needs a higher temperature for tempering than ordinary steel, and should be hardened only between yellow, red, and white. Chisels made of tungsten steel should be drawn between cherry-red and blue, and stand well on iron and steel. Tempering is best done in a mixture of 5 parts of yellow rosin, 3 parts of tar, and 2 parts of tallow, and then the article is once more heated and then tempered as usual in water of about 15° C.

**Fluid-compressed [Steel by the "Whitworth Process."** (Proc. Inst. M. E., May, 1887, p. 167.)—In this system a gradually increasing pressure up to 6 or 8 tons per square inch is applied to the fluid ingot, and within half an hour or less after the application of the pressure the column of fluid steel is shortened 1½ inch per foot or one-eighth of its length; the pressure is then kept on for several hours, the result being that the metal is compressed into a perfectly solid and homogeneous material, free from blow-holes.

In large gun-ring ingots during cooling the carbon is driven to the centre, the centre containing 0.8 carbon and the outer ring 0.3. The centre is bored out until a test shows that the inside of the ring contains the same percentage of carbon as the outside.

Fluid-compressed steel is made by the Bethlehem Iron Co. for gun and other heavy forgings.

## CRUCIBLE STEEL.

**Selection of Grades by the Eye, and Effect of Heat Treatment.** (J. W. Langley, *Amer. Chemist*, November, 1876.)—In 1874, Miller, Metcalf & Parkin, of Pittsburgh, selected eight samples of steel which were believed to form a set of graded specimens, the order being based on the quantity of carbon which they were supposed to contain. They were numbered from one to eight. On analysis, the quantity of carbon was found to follow the order of the numbers, while the other elements present—silicon, phosphorus, and sulphur—did not do so. The method of selection is described as follows :

The steel is melted in black-lead crucibles capable of holding about eighty pounds; when thoroughly fluid it is poured into cast-iron moulds, and when cold the top of the ingot is broken off, exposing a freshly-fractured surface. The appearance presented is that of confused groups of crystals, all appearing to have started from the outside and to have met in the centre; this general form is common to all ingots of whatever composition, but to the trained eye, and only to one long and critically exercised, a minute but in-

describable difference is perceived between varying samples of steel, and this difference is now known to be owing almost wholly to variations in the amount of combined carbon, as the following table will show. Twelve samples selected by the eye alone, and analyses of drillings taken direct from the ingot before it had been heated or hammered, gave results as below:

Ingot Nos.	Iron by Diff.	Carbon.	Diff. of Carbon.	Silicon.	Phos.	Sulph.
1	99.614	.302	.....	.019	.047	.018
2	99.455	.490	.188	.034	.005	.016
3	99.363	.529	.039	.043	.047	.018
4	99.270	.649	.120	.039	.030	.012
5	99.119	.801	.152	.029	.035	.016
6	99.086	.841	.040	.039	.024	.010
7	99.044	.867	.026	.057	.014	.018
8	99.040	.871	.004	.053	.024	.012
9	98.900	.955	.084	.059	.070	.016
10	98.861	1.005	.050	.088	.034	.012
11	98.752	1.058	.053	.120	.064	.006
12	98.834	1.079	.021	.039	.044	.004

Here the carbon is seen to increase in quantity in the order of the numbers, while the other elements, with the exception of total iron, bear no relation to the numbers on the samples. The mean difference of carbon is .071.

In mild steels the discrimination is less perfect.

The appearance of the fracture by which the above twelve selections were made can only be seen in the cold ingot before any operation, except the original one of casting, has been performed upon it. As soon as it is hammered, the structure changes in a remarkable manner, so that all trace of the primitive condition appears to be lost.

Another method of rendering visible to the eye the molecular and chemical changes which go on in steel is by the process of hardening or tempering. When the metal is heated and plunged into water it acquires an increase of hardness, but a loss of ductility. If the heat to which the steel has been raised just before plunging is too high, the metal acquires intense hardness, but it is so brittle as to be worthless; the fracture is of a bright, granular, or sandy character. In this state it is said to be burned, and it cannot again be restored to its former strength and ductility by annealing; it is ruined for all practical purposes, but in just this state it again shows differences of structure corresponding with its content in carbon. The nature of these changes can be illustrated by plunging a bar highly heated at one end and cold at the other into water, and then breaking it off in pieces of equal length, when the fractures will be found to show appearances characteristic of the temperature to which the sample was raised.

The specific gravity of steel is influenced not only by its chemical analysis, but by the heat to which it is subjected, as is shown by the following table (densities referred to 60° F.):

*Specific gravities of twelve samples of steel from the ingot; also of six hammered bars, each bar being overheated at one end and cold at the other, in this state plunged into water, and then broken into pieces of equal length.*

\* Order of samples from bar.

**Effect of Heat on the Grain of Steel.** (W. Metcalf,—Jeans on Steel, p. 642.)—A simple experiment will show the alteration produced in a high-carbon steel by different methods of hardening. If a bar of such steel be nicked at about 9 or 10 places, and about half an inch apart, a suitable specimen is obtained for the experiment. Place one end of the bar in a good fire, so that the first nicked piece is heated to whiteness, while the rest of the bar, being out of the fire, is heated up less and less as we approach the other end. As soon as the first piece is at a good white heat, which of course burns a high carbon steel, and the temperature of the rest of the bar gradually passes down to a very dull red, the metal should be taken out of the fire and suddenly plunged in cold water, in which it should be left till quite cold. It should then be taken out and carefully dried. An examination with a file will show that the first piece has the greatest hardness, while the last piece is the softest, the intermediate pieces gradually passing from one condition to the other. On now breaking off the pieces at each nick it will be seen that very considerable and characteristic changes have been produced in the appearance of the metal. The first burnt piece is very open or crystalline in fracture; the succeeding pieces become closer and closer in the grain until one piece is found to possess that perfectly even grain and velvet-like appearance which is so much prized by experienced steel users. The first pieces also, which have been too much hardened, will probably be cracked; those at the other end will not be hardened through. Hence if it be desired to make the steel hard and strong, the temperature used must be high enough to harden the metal through, but not sufficient to open the grain.

**Changes in Ultimate Strength and Elasticity due to Hammering, Annealing, and Tempering.** (J. W. Langley, Trans. A. S. C. E. 1892.)—The following table gives the result of tests made on some round steel bars, all from the same ingot, which were tested by tensile stresses, and also by bending till fracture took place:

Number.	Treatment.	Angle of cold bend, degrees.		Carbon.		Diameter, in.	Elastic limit, pounds per square inch.	Tensile, pounds per square inch.	Elongation, per cent.	Red area, per cent.
		Total.	Semi-graphite.	Total.	Semi-graphite.					
1	Cold-hammered bar	153	1.25	.47	.575	92,420	141,500	2.00	2.42	
2	Bar drawn black....	75	1.25	.47	.577	114,700	138,400	6.00	12.45	
3	Bar annealed .....	175	1.31	.70	.580	68,110	98,410	10.00	11.69	
4	Bar hardened and drawn black .....	30	1.09	.36	.578	152,800	248,700	8.33	17.9	

The total carbon given in the table was found by the color test, which is affected, not only by the total carbon, but by the condition of the carbon.

The analysis of the steel was:

Silicon .....	.242	Manganese.....	.24
Phosphorus.....	.02	Carbon (true total carbon, by combustion)...	1.31
Sulphur .....	.009		

**Heating Tool Steel.** (Crescent Steel Co., Pittsburg, Pa.)—There are three distinct stages or times of heating: First, for forging; second, for hardening; third, for tempering.

The first requisite for a good heat for forging is a clean fire and plenty of fuel, so that jets of hot air will not strike the corners of the piece; next, the fire should be regular, and give a good uniform heat to the whole part to be forged. It should be keen enough to heat the piece as rapidly as may be, and allow it to be thoroughly heated through, without being so fierce as to overheat the corners.

Steel should not be left in the fire any longer than is necessary to heat it clear through, as "soaking" in fire is very injurious; and, on the other hand, it is necessary that it should be hot through, to prevent surface cracks.

By observing these precautions a piece of steel may always be heated safely, up to even a bright yellow heat, when there is much forging to be done on it.

The best and most economical of welding fluxes is clean, crude borax, which should be first thoroughly melted and then ground to fine powder.

After the steel is properly heated, it should be forged to shape as quickly as possible; and just as the red heat is leaving the parts intended for cutting edges, these parts should be refined by rapid, light blows, continued until the red disappears.

For the second stage of heating, for hardening, great care should be used: first, to protect the cutting edges and working parts from heating more rapidly than the body of the piece; next, that the whole part to be hardened be heated uniformly through, without any part becoming visibly hotter than the other. A uniform heat, as low as will give the required hardness, is the best for hardening.

For every variation of heat, which is great enough to be seen, there will result a variation in grain, which may be seen by breaking the piece: and for every such variation in temperature, there is a very good chance for a crack to be seen. Many a costly tool is ruined by inattention to this point.

The effect of too high heat is to open the grain; to make the steel coarse. The effect of an irregular heat is to cause irregular grain, irregular strains, and cracks.

As soon as the piece is properly heated for hardening, it should be promptly and thoroughly quenched in plenty of the cooling medium, water, brine, or oil, as the case may be.

An abundance of the cooling bath, to do the work quickly and uniformly all over, is very necessary to good and safe work.

To harden a large piece safely a running stream should be used.

Much uneven hardening is caused by the use of too small baths.

For the third stage of heating, to temper, the first important requisite is again uniformity. The next is time; the more slowly a piece is brought down to its temper, the better and safer is the operation.

When expensive tools are to be made it is a wise precaution to try small pieces of the steel at different temperatures, so as to find out how low a heat will give the necessary hardness. The lowest heat is the best for any steel.

**Heating to Forge.**—The trouble in the forge fire is usually uneven heat, and not too high heat. Suppose the piece to be forged has been put into a very hot fire, and forced as quickly as possible to a high yellow heat, so that it is almost up to the scintillating point. If this be done, in a few minutes the outside will be quite soft and in a nice condition for forging, while the middle parts will not be more than red-hot. Now let the piece be placed under the hammer and forged, and the soft outside will yield so much more readily than the hard inside, that the outer particles will be torn asunder, while the inside will remain sound.

Suppose the case to be reversed and the inside to be much hotter than the outside; that is, that the inside shall be in a state of semi-fusion, while the outside is hard and firm. Now let the piece be forged, and the outside will be all sound and the whole piece will appear perfectly good until it is cropped, and then it is found to be hollow inside.

In either case, if the piece had been heated soft all through, or if it had been only red-hot all through, it would have forged perfectly sound.

In some cases a high heat is more desirable to save heavy labor but in every case where a fine steel is to be used for cutting purposes it must be borne in mind that very heavy forging refines the bars as they slowly cool, and if the smith heats such refined bars until they are soft, he raises the grain, makes them coarse, and he cannot get them fine again unless he has a very heavy steam-hammer at command and knows how to use it well.

**Annealing.** (Crescent Steel Co.)—Annealing or softening is accomplished by heating steel to a red heat and then cooling it very slowly, to prevent it from getting hard again.

The higher the degree of heat, the more will steel be softened, until the limit of softness is reached, when the steel is melted.

It does not follow that the higher a piece of steel is heated the softer it will be when cooled, no matter how slowly it may be cooled; this is proved by the fact that an ingot is always harder than a rolled or hammered bar made from it.

Therefore there is nothing gained by heating a piece of steel hotter than a good, bright, cherry-red; on the contrary, a higher heat has several disadvantages: First. If carried too far, it may leave the steel actually harder than a good red heat would leave it. Second. If a scale is raised on the steel, this scale will be harsh, granular oxide of iron, and will spoil the tools used to cut it. Third. A high scaling heat continued for a little time

changes the structure of the steel, makes it brittle, liable to crack in hardening, and impossible to refine.

To anneal any piece of steel, heat it red-hot; heat it uniformly and heat it through, taking care not to let the ends and corners get too hot.

As soon as it is hot, take it out of the fire, the sooner the better, and cool it as slowly as possible. A good rule for heating is to heat it at so low a red that when the piece is cold it will still show the blue gloss of the oxide that was put there by the hammer or the rolls.

Steel annealed in this way will cut very soft; it will harden very hard, without cracking; and when tempered it will be very strong, nicely refined, and will hold a keen, strong edge.

**Tempering.**—Tempering steel is the act of giving it, after it has been shaped, the hardness necessary for the work it has to do. This is done by first hardening the piece, generally a good deal harder than is necessary, and then toughening it by slow heating and gradual softening until it is just right for work.

A piece of steel properly tempered should always be finer in grain than the bar from which it is made. If it is necessary, in order to make the piece as hard as is required, to heat it so hot that after being hardened the grain will be as coarse as or coarser than the grain in the original bar, then the steel itself is of too low carbon for the desired work.

If a great degree of hardness is not desired, as in the case of taps, and most tools of complicated form, and it is found that at a moderate heat the tools are too hard and are liable to crack, the smith should first use a lower heat in order to save the tools already made, and then notify the steelmaker that his steel is too high, so as to prevent a recurrence of the trouble.

For descriptions of various methods of tempering steel, see "Tempering of Metals," by Joshua Rose, in *App. Cyc. Mech.*, vol. ii. p. 863; also, "Wrinkles and Recipes," from the *Scientific American*. In both of these works Mr. Rose gives a "color scale," lithographed in colors, by which the following is a list of the tools in their order on the color scale, together with the approximate color and the temperature at which the color appears on brightened steel when heated in the air:

Scrapers for brass; <i>very pale yellow</i> , 430° F.	Hand-plane irons.
Steel-engraving tools.	Twist-drills.
Slight turning tools.	Flat drills for brass.
Hammer faces.	Wood-boring cutters.
Planer tools for steel.	Drifts.
Ivory-cutting tools.	Coopers' tools.
Planer tools for iron.	Edging cutters; <i>light purple</i> , 530° F.
Paper-cutters.	Augers.
Wood-engraving tools.	Dental and surgical instruments.
Bone cutting tools.	Cold chisels for steel.
Milling-cutters; <i>straw yellow</i> , 460° F.	Axes; <i>dark purple</i> , 550° F.
Wire-drawing dies.	Gimlets.
Boring-cutters.	Cold chisels for cast iron.
Leather-cutting dies.	Saws for bone and ivory.
Screw-cutting dies.	Needles.
Inserted saw-teeth.	Firmer-chisels.
Taps.	Hack-saws.
Rock-drills.	Framing-chisels.
Chasers.	Cold chisels for wrought iron.
Punches and dies.	Moulding and planing cutters to be filed.
Penknives.	Circular saws for metal.
Reamers.	Screw-drivers.
Half-round bits.	Springs.
Planing and moulding cutters.	Saws for wood.
Stone-cutting tools; <i>brown yellow</i> , 500° F.	<i>Dark blue</i> , 570° F.
Gouges.	<i>Pale blue</i> , 610°.
	<i>Blue tinged with green</i> , 630°.

## MECHANICS.

**FORCE, STATICAL MOMENT, EQUILIBRIUM, ETC.**

MECHANICS is the science that treats of the action of force upon bodies.

**A Force** is anything that tends to change the state of a body with respect to rest or motion. If a body is at rest, anything that tends to put it in motion is a force; if a body is in motion, anything that tends to change either its direction or its rate of motion is a force.

A force should always mean the pull, pressure, rub, attraction (or repulsion) of one body upon another, and always implies the existence of a simultaneous equal and opposite force exerted by that other body on the first body, i.e., the *reaction*. In no case should we call anything a force unless we can conceive of it as capable of measurement by a spring-balance, and are able to say from what other body it comes. (I. P. Church.)

Forces may be divided into two classes, extraneous and molecular: extraneous forces act on bodies from without; molecular forces are exerted between the neighboring particles of bodies.

*Extraneous forces* are of two kinds, pressures and moving forces: pressures simply tend to produce motion; moving forces actually produce motion. Thus, if gravity act on a fixed body, it creates pressure; if on a free body, it produces motion.

*Molecular forces* are of two kinds, attractive and repellent: attractive forces tend to bind the particles of a body together; repellent forces tend to thrust them asunder. Both kinds of molecular forces are continually exerted between the molecules of bodies, and on the predominance of one or the other depends the physical state of a body, as solid, liquid, or gaseous.

**The Unit of Force** used in engineering, by English writers, is the pound avoirdupois. (For some scientific purposes, as in electro-dynamics, forces are sometimes expressed in "absolute units.") The absolute unit of force is that force which acting on a unit of mass during a unit of time produces a unit of velocity; in English measures, that force which acting on the mass whose weight is one pound in London will in one second produce a velocity of one foot per second =  $1 \div 32.187$  of the weight of the standard pound avoirdupois at London. In the French C. G. S. or centimetre-gramme second system it is the force which acting on the mass whose weight is one gramme at Paris will produce in one second a velocity of one centimetre per second. This unit is called a "dyne" =  $1/981$  gramme at Paris.)

**Inertia** is that property of a body by virtue of which it tends to continue in the state of rest or motion in which it may be placed, until acted on by some force.

**Newton's Laws of Motion.**—1st Law. If a body be at rest, it will remain at rest; or if in motion, it will move uniformly in a straight line till acted on by some force.

2d Law. If a body be acted on by several forces, it will obey each as though the others did not exist, and this whether the body be at rest or in motion.

3d Law. If a force act to change the state of a body with respect to rest or motion, the body will offer a resistance equal and directly opposed to the force. Or, to every action there is opposed an equal and opposite reaction.

**Graphic Representation of a Force.**—Forces may be represented geometrically by straight lines, proportional to the forces. A force is given when we know its intensity, its point of application, and the direction in which it acts. When a force is represented by a line, the length of the line represents its intensity; one extremity represents the point of application; and an arrow-head at the other extremity shows the direction of the force.

**Composition of Forces** is the operation of finding a single force whose effect is the same as that of two or more given forces. The required force is called the resultant of the given forces.

**Resolution of Forces** is the operation of finding two or more forces whose combined effect is equivalent to that of a given force. The required forces are called components of the given force.

The resultant of two forces applied at a point, and acting in the same direction, is equal to the sum of the forces. If two forces act in opposite directions, their resultant is equal to their difference, and it acts in the direction of the greater.

If any number of forces be applied at a point, some in one direction and others in a contrary direction, their resultant is equal to the sum of those that act in one direction, diminished by the sum of those that act in the opposite direction; or, the resultant is equal to the algebraic sum of the components.

**Parallelogram of Forces.**—If two forces acting on a point be represented in direction and intensity by adjacent sides of a parallelogram, their resultant will be represented by that diagonal of the parallelogram

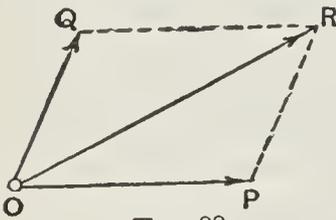

FIG. 88.

which passes through the point. Thus  $OR$ , Fig. 88, is the resultant of  $OQ$  and  $OP$ .

**Polygon of Forces.**—If several forces are applied at a point and act in a single plane, their resultant is found as follows:

Through the point draw a line representing the first force; through the extremity of this draw a line representing the second force; and so on, throughout the system; finally, draw a line from the starting-point to the extremity of the last line

drawn, and this will be the resultant required.

Suppose the body  $A$ , Fig. 89, to be urged in the directions  $A1$ ,  $A2$ ,  $A3$ ,  $A4$ , and  $A5$  by forces which are to each other as the lengths of those lines. Suppose these forces to act successively and the body to first move from  $A$  to 1; the second force  $A2$  then acts and finding the body at 1 would take it to 2'; the third force would then carry it to 3', the fourth to 4', and the fifth to 5'. The line  $A5'$  represents in magnitude and direction the resultant of all the forces considered. If there had been an additional force,  $Ax$ , in the group, the body would be returned by that force to its original position, supposing the forces to act successively, but if they had acted simultaneously the body would never have moved at all; the tendencies to motion balancing each other.

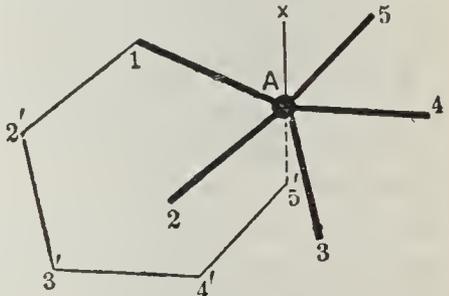

FIG. 89.

It follows, therefore, that if the several forces which tend to move a body can be represented in magnitude and direction by the sides of a closed polygon taken in order, the body will remain at rest; but if the forces are represented by the sides of an open polygon, the body will move and the direction will be represented by the straight line which closes the polygon.

**Twisted Polygon.**—The rule of the polygon of forces holds true even when the forces are not in one plane. In this case the lines  $A1$ ,  $1-2'$ ,  $2'-3'$ , etc., form a twisted polygon, that is, one whose sides are not in one plane.

**Parallelepipedon of Forces.**—If three forces acting on a point be represented by three edges of a parallelepipedon which meet in a common point, their resultant will be represented by the diagonal of the parallelepipedon that passes through their common point.

Thus  $OR$ , Fig. 90, is the resultant of  $OQ$ ,  $OS$ , and  $OP$ .  $OM$  is the resultant of  $OP$  and  $OQ$ , and  $OR$  is the resultant of  $OM$  and  $OS$ .

**Moment of a Force.**—The moment of a force (sometimes called statical moment), with respect to a point, is the product of the force by the perpendicular distance from the point to the direction of the force. The fixed point is called the centre of mo-

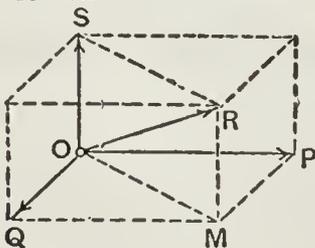

FIG. 90.

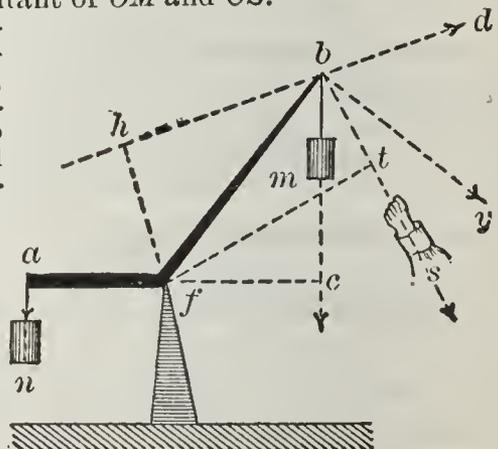

FIG. 91.

ments ; the perpendicular distance is the lever-arm of the force; and the moment itself measures the tendency of the force to produce rotation about the centre of moments.

If the force is expressed in pounds and the distance in feet, the moment is expressed in foot-pounds. It is necessary to observe the distinction between foot-pounds of statical moment and foot-pounds of work or energy. (See Work.)

In the bent lever, Fig. 91 (from Trautwine), if the weights  $n$  and  $m$  represent forces, their moments about the point  $f$  are respectively  $n \times af$  and  $m \times fc$ . If instead of the weight  $m$  a pulling force to balance the weight  $n$  is applied in the direction  $bs$ , or  $by$  or  $bd$ ,  $s$ ,  $y$ , and  $d$  being the amounts of these forces, their respective moments are  $s \times ft$ ,  $y \times fb$ ,  $d \times fh$ .

If the forces acting on the lever are in equilibrium it remains at rest, and the moments on each side of  $f$  are equal, that is,  $n \times af = m \times fc$ , or  $s \times ft$ , or  $y \times fb$ , or  $d \times fh$ .

The moment of the resultant of any number of forces acting together in the same plane is equal to the algebraic sum of the moments of the forces taken separately.

**Statical Moment. Stability.**—The statical moment of a body is the product of its weight by the distance of its line of gravity from some assumed line of rotation. The line of gravity is a vertical line drawn from its centre of gravity through the body. The stability of a body is that resistance which its weight alone enables it to oppose against forces tending to overturn it or to slide it along its foundation.

To be safe against turning on an edge the moment of the forces tending to overturn it, taken with reference to that edge, must be less than the statical moment. When a body rests on an inclined plane, the line of gravity being vertical, falls toward the lower edge of the body, and the condition of its not being overturned by its own weight is that the line of gravity must fall within this edge. In the case of an inclined tower resting on a plane the same condition holds—the line of gravity must fall within the base. The condition of stability against sliding along a horizontal plane is that the horizontal component of the force exerted tending to cause it to slide shall be less than the product of the weight of the body into the coefficient of friction between the base of the body and its supporting plane. This coefficient of friction is the tangent of the angle of repose, or the maximum angle at which the supporting plane might be raised from the horizontal before the body would begin to slide. (See Friction.)

**The Stability of a Dam** against overturning about its lower edge is calculated by comparing its statical moment referred to that edge with the resultant pressure of the water against its upper side. The horizontal pressure on a square foot at the bottom of the dam is equal to the weight of a column of water of one square foot in section, and of a height equal to the distance of the bottom below water-level; or, if  $H$  is the height, the pressure at the bottom per square foot =  $62.4 \times H$  lbs. At the water-level the pressure is zero, and it increases uniformly to the bottom, so that the sum of the pressures on a vertical strip one foot in breadth may be represented by the area of a triangle whose base is  $62.4 \times H$  and whose altitude is  $H$ , or  $62.4H^2 \div 2$ . The centre of gravity of a triangle being  $\frac{1}{3}$  of its altitude, the resultant of all the horizontal pressures may be taken as equivalent to the sum of the pressures acting at  $\frac{1}{3}H$ , and the moment of the sum of the pressures is therefore  $62.4 \times H^3 \div 6$ .

**Parallel Forces.**—If two forces are parallel and act in the same direction, their resultant is parallel to both, and lies between them, and the intensity of the resultant is equal to the sum of the intensities of the two forces. Thus in Fig. 91 the resultant of the forces  $n$  and  $m$  acts vertically downward at  $f$ , and is equal to  $n + m$ .

If two parallel forces act at the extremities of a straight line and in the same direction, the resultant divides the line joining the points of application of the components, inversely as the components. Thus in Fig. 91,  $m : n :: af : fc$ ; and in Fig. 92,  $P : Q :: SN : SM$ .

The resultant of two parallel forces acting in opposite directions is parallel to both, lies without both, on the side and in the direction of the greater, and its intensity is equal to the difference of the intensities of the two forces.

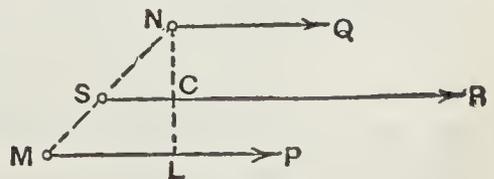

FIG. 92.

Thus the resultant of the two forces  $Q$  and  $P$ , Fig. 93, is equal to  $Q - P = R$ . Of any two parallel forces and their resultant each is proportional to the distance between the other two; thus in both Figs. 92 and 93,  $P : Q : R :: SN : SM : MN$ .

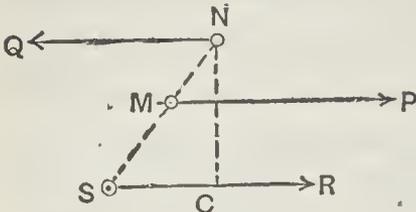

FIG. 93.

**Couples.**—If  $P$  and  $Q$  be equal and act in opposite directions,  $R = 0$ ; that is, they have no resultant. Two such forces constitute what is called a couple.

The tendency of a couple is to produce rotation; the measure of this tendency, called the *moment of the couple*, is the

product of one of the forces by the distance between the two.

Since a couple has no single resultant, no single force can balance a couple. To prevent the rotation of a body acted on by a couple the application of two other forces is required, forming a second couple. Thus in Fig. 94,  $P$  and  $Q$  forming a couple, may be balanced by a second couple formed by  $R$  and  $S$ . The point of application of either  $R$  or  $S$  may be a fixed pivot or axis.

Moment of the couple  $PQ = P(c + b + a) =$  moment of  $RS = Rb$ . Also,  $P + R = Q + S$ .

The forces  $R$  and  $S$  need not be parallel to  $P$  and  $Q$ , but if not, then their components parallel to  $PQ$  are to be taken instead of the forces themselves.

**Equilibrium of Forces.**—A system of forces applied at points of a solid body will be in equilibrium when they have no tendency to produce motion, either of translation or of rotation.

The conditions of equilibrium are: 1. The algebraic sum of the components of the forces in the direction of any three rectangular axes must be separately equal to 0.

2. The algebraic sum of the moments of the forces, with respect to any three rectangular axes, must be separately equal to 0.

If the forces lie in a plane: 1. The algebraic sum of the components of the forces, in the direction of any two rectangular axes, must be separately equal to 0.

2. The algebraic sum of the moments of the forces, with respect to any point in the plane, must be equal to 0.

If a body is restrained by a fixed axis, as in case of a pulley, or wheel and axle, the forces will be in a equilibrium when the algebraic sum of the moments of the forces with respect to the axis is equal to 0.

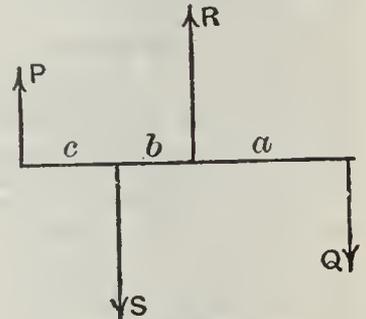

FIG. 94.

## CENTRE OF GRAVITY.

The centre of gravity of a body, or of a system of bodies rigidly connected together, is that point about which, if suspended, all the parts will be in equilibrium, that is, there will be no tendency to rotation. It is the point through which passes the resultant of the efforts of gravitation on each of the elementary particles of a body. In bodies of equal heaviness throughout, the centre of gravity is the centre of magnitude.

(The centre of magnitude of a figure is a point such that if the figure be divided into equal parts the distance of the centre of magnitude of the whole figure from any given plane is the mean of the distances of the centres of magnitude of the several equal parts from that plane.)

If a body be suspended at its centre of gravity, it will be in equilibrium in all positions. If it be suspended at a point out of its centre of gravity, it will swing into a position such that its centre of gravity is vertically beneath its point of suspension.

To find the centre of gravity of any plane figure mechanically, suspend the figure by any point near its edge, and mark on it the direction of a plumb-line hung from that point; then suspend it from some other point, and again mark the direction of the plumb-line in like manner. Then the centre of gravity of the surface will be at the point of intersection of the two marks of the plumb-line.

**The Centre of Gravity of Regular Figures**, whether plane or solid, is the same as their geometrical centre; for instance, a straight line,

parallelogram, regular polygon, circle, circular ring, prism, cylinder, sphere, spheroid, middle frustums of spheroid, etc.

*Of a triangle:* On a line drawn from any angle to the middle of the opposite side, at a distance of one third of the line from the side; or at the intersection of such lines drawn from any two angles.

*Of a trapezium or trapezoid:* Draw a diagonal, dividing it into two triangles. Draw a line joining their centres of gravity. Draw the other diagonal, making two other triangles, and a line joining their centres. The intersection of the two lines is the centre of gravity required.

*Of a sector of a circle:* On the radius which bisects the arc,  $2cr \div 3l$  from the centre,  $c$  being the chord,  $r$  the radius, and  $l$  the arc.

*Of a semicircle:* On the middle radius,  $.4244r$  from the centre.

*Of a quadrant:* On the middle radius,  $.6002r$  from the centre.

*Of a segment of a circle:*  $c^3 \div 12a$  from the centre.  $c$  = chord,  $a$  = area.

*Of a parabolic surface:* In the axis,  $3/5$  of its length from the vertex.

*Of a semi-parabola (surface):*  $3/5$  length of the axis from the vertex, and  $3/8$  of the semi-base from the axis.

*Of a cone or pyramid:* In the axis,  $1/4$  of its length from the base.

*Of a paraboloid:* In the axis,  $2/3$  of its length from the vertex.

*Of a cylinder, or regular prism:* In the middle point of the axis.

*Of a frustum of a cone or pyramid:* Let  $a$  = length of a line drawn from the vertex of the cone when complete to the centre of gravity of the base, and  $a'$  that portion of it between the vertex and the top of the frustum; then distance of centre of gravity of the frustum from centre of gravity of its

$$\text{base} = \frac{a}{4} - \frac{3a'^3}{4(a^2 + aa' + a'^2)}$$

*For two bodies,* fixed one at each end of a straight bar, the common centre of gravity is in the bar, at that point which divides the distance between their respective centres of gravity in the inverse ratio of the weights. In this solution the weight of the bar is neglected. But it may be taken as a third body, and allowed for as in the following directions:

For more than two bodies connected in one system: Find the common centre of gravity of two of them; and find the common centre of these two jointly with a third body, and so on to the last body of the group.

*Another method,* by the principle of moments: To find the centre of gravity of a system of bodies, or a body consisting of several parts, whose several centres are known. If the bodies are in a plane, refer their several centres to two rectangular co-ordinate axes. Multiply each weight by its distance from one of the axes, add the products, and divide the sum by the sum of the weights: the result is the distance of the centre of gravity from that axis. Do the same with regard to the other axis. If the bodies are not in a plane, refer them to three planes at right angles to each other, and determine the mean distance of the sum of the weights from each of the three planes.

### MOMENT OF INERTIA.

The moment of inertia of the weight of a body with respect to an axis is the algebraic sum of the products obtained by multiplying the weight of each elementary particle by the square of its distance from the axis. If the moment of inertia with respect to any axis =  $I$ , the weight of any element of the body =  $w$ , and its distance from the axis =  $r$ , we have  $I = \sum(wr^2)$ .

The moment of inertia varies, in the same body, according to the position of the axis. It is the least possible when the axis passes through the centre of gravity. To find the moment of inertia of a body, referred to a given axis, divide the body into small parts of regular figure. Multiply the weight of each part by the square of the distance of its centre of gravity from the axis. The sum of the products is the moment of inertia. The value of the moment of inertia thus obtained will be more nearly exact, the smaller and more numerous the parts into which the body is divided.

**MOMENTS OF INERTIA OF REGULAR SOLIDS.**—Rod, or bar, of uniform thickness, with respect to an axis perpendicular to the length of the rod,

$$I = W \left( \frac{l^2}{3} + d^2 \right), \dots \dots \dots (1)$$

$W$  = weight of rod,  $2l$  = length,  $d$  = distance of centre of gravity from axis.

Thin circular plate, axis in its own plane,  $\left\{ I = W \left( \frac{r^2}{4} + d^2 \right); \dots \dots \dots (2) \right.$

$r$  = radius of plate.

Circular plate, axis perpendicular to the plate,  $\left\{ I = W \left( \frac{r^2}{2} + d^2 \right) \dots \dots \dots (3) \right.$

Circular ring, axis perpendicular to its own plane,  $\left\{ I = W \left( \frac{r^2 + r'^2}{2} + d^2 \right) \dots \dots \dots (4) \right.$

$r$  and  $r'$  are the exterior and interior radii of the ring.

Cylinder, axis perpendicular to the axis of the cylinder,  $\left\{ I = W \left( \frac{r^2}{4} + \frac{l^2}{3} + d^2 \right) \dots \dots \dots (5) \right.$

$r$  = radius of base,  $2l$  = length of the cylinder.

By making  $d = 0$  in any of the above formulæ we find the moment of inertia for a parallel axis through the centre of gravity.

The moment of inertia,  $\Sigma wr^2$ , numerically equals the weight of a body which, if concentrated at the distance unity from the axis of rotation, would require the same work to produce a given increase of angular velocity that the actual body requires. It bears the same relation to angular acceleration which weight does to linear acceleration (Rankine). The term moment of inertia is also used in regard to areas, as the cross-sections of beams under strain. In this case  $I = \Sigma ar^2$ , in which  $a$  is any elementary area, and  $r$  its distance from the centre. (See under Strength of Materials, p. 247.) Some writers call  $\Sigma mr^2 = \Sigma wr^2 \div g$  the moment of inertia.

**CENTRE AND RADIUS OF GYRATION.**

The centre of gyration, with reference to an axis, is a point at which, if the entire weight of a body be concentrated, its moment of inertia will remain unchanged; or, in a revolving body, the point in which the whole weight of the body may be conceived to be concentrated, as if a pound of platinum were substituted for a pound of revolving feathers, the angular velocity and the accumulated work remaining the same. The distance of this point from the axis is the radius of gyration. If  $W =$  the weight of a body,  $I = \Sigma wr^2 =$  its moment of inertia, and  $k =$  its radius of gyration,

$$I = Wk^2 = \Sigma wr^2; \quad k = \sqrt{\frac{\Sigma wr^2}{W}}$$

The moment of inertia = the weight  $\times$  the square of the radius of gyration.

To find the radius of gyration divide the body into a considerable number of equal small parts—the more numerous the more nearly exact is the result,—then take the mean of all the squares of the distances of the parts from the axis of revolution, and find the square root of the mean square. Or, if the moment of inertia is known, divide it by the weight and extract the square root. For radius of gyration of an area, as a cross-section of a beam, divide the moment of inertia of the area by the area and extract the square root.

The radius of gyration is the least possible when the axis passes through the centre of gravity. This minimum radius is called the principal radius of gyration. If we denote it by  $k$  and any other radius of gyration by  $k'$ , we have for the five cases given under the head of moment of inertia above the following values :

(1) Rod, axis perpen. to length,  $\left\{ k = l \sqrt{\frac{1}{3}}; \quad k' = \sqrt{\frac{l^2}{3} + d^2} \right.$

(2) Circular plate, axis in its plane,  $\left\{ k = \frac{r}{2}; \quad k' = \sqrt{\frac{r^2}{4} + d^2} \right.$

(3) Circular plate, axis perpen. to plane,  $\left\{ k = r \sqrt{\frac{1}{2}}; \quad k' = \sqrt{\frac{r^2}{2} + d^2} \right.$

(4) Circular ring, axis perpen. to plane,  $\left\{ k = \sqrt{\frac{r^2 + r'^2}{2}}; \quad k' = \sqrt{\frac{r^2 + r'^2}{2} + d^2} \right.$

(5) Cylinder, axis perpen. to length,  $\left\{ k = \sqrt{\frac{r^2}{4} + \frac{l^2}{3}}; \quad k' = \sqrt{\frac{r^2}{4} + \frac{l^2}{3} + d^2} \right.$

**Principal Radii of Gyration and Squares of Radii of Gyration.**

(For radii of gyration of sections of columns, see page 249.)

Surface or Solid.	Rad. of Gyration.	Square of R. of Gyration.
Parallelogram: } axis at its base..... height $h$ } " mid-height.....	.5773 $h$ .2886 $h$	$\frac{1}{3}h^2$ $\frac{1}{12}h^2$

Ellipsoid: semi-axes $a, b, c$ ; revol- ving on axis $2a$ .....	.4472 $\sqrt{b^2 + c^2}$	$\frac{b^2 + c^2}{5}$
Spherical shell: radii $R, r$ , revolving } on its diam. .... }	.6325 $\sqrt{\frac{R^5 - r^5}{R^3 - r^3}}$	$\frac{2}{5} \frac{R^5 - r^5}{R^3 - r^3}$
Same: very thin, radius $r$ .....	8165 $r$	$\frac{2}{3}r^2$
Solid cone: $r$ = rad. of base, rev. on } axis..... }	.5477 $r$	$0.3r^2$

**CENTRES OF OSCILLATION AND OF PERCUSSION.**

**Centre of Oscillation.**—If a body oscillate about a fixed horizontal axis, not passing through its centre of gravity, there is a point in the line drawn from the centre of gravity perpendicular to the axis whose motion is the same as it would be if the whole mass were collected at that point and allowed to vibrate as a pendulum about the fixed axis. This point is called the centre of oscillation.

**The Radius of Oscillation,** or distance of the centre of oscillation from the point of suspension = the square of the radius of gyration  $\div$  distance of the centre of gravity from the point of suspension or axis. The centres of oscillation and suspension are convertible.

If a straight line, or uniform thin bar or cylinder, be suspended at one end, oscillating about it as an axis, the centre of oscillation is at  $\frac{2}{3}$  the length of

the rod from the axis. If the point of suspension is at  $\frac{1}{3}$  the length from the end, the centre of oscillation is also at  $\frac{2}{3}$  the length from the axis, that is, it is at the other end. In both cases the oscillation will be performed in the same time. If the point of suspension is at the centre of gravity, the length of the equivalent simple pendulum is infinite, and therefore the time of vibration is infinite.

For a sphere suspended by a cord,  $r$  = radius,  $h$  = distance of axis of motion from the centre of the sphere,  $h'$  = distance of centre of oscillation from centre of the sphere,  $l$  = radius of oscillation =  $h + h' = h + \frac{2}{5} \frac{r^2}{h}$ .

If the sphere vibrate about an axis tangent to its surface,  $h = r$ , and  $l = r + \frac{2}{5}r$ . If  $h = 10r$ ,  $l = 10r + \frac{2}{25}r$ .

Lengths of the radius of oscillation of a few regular plane figures or thin plates, suspended by the vertex or uppermost point.

1st. When the vibrations are flatwise, or perpendicular to the plane of the figure:

In an isosceles triangle the radius of oscillation is equal to  $\frac{3}{4}$  of the height of the triangle.

In a circle,  $\frac{5}{8}$  of the diameter.

In a parabola,  $\frac{5}{7}$  of the height.

2d. When the vibrations are edgewise, or in the plane of the figure:

In a circle the radius of oscillation is  $\frac{3}{4}$  of the diameter.

In a rectangle suspended by one angle,  $\frac{2}{3}$  of the diagonal.

In a parabola, suspended by the vertex,  $\frac{5}{7}$  of the height, plus  $\frac{1}{3}$  of the parameter.

In a parabola, suspended by the middle of the base,  $\frac{4}{7}$  of the height plus  $\frac{1}{2}$  the parameter.

**Centre of Percussion.**—The centre of percussion of a body oscillating about a fixed axis is the point at which, if a blow is struck by the body, the percussive action is the same as if the whole mass of the body were concentrated at the point. This point is identical with the centre of oscillation.

**THE PENDULUM.**

A body of any form suspended from a fixed axis about which it oscillates by the force of gravity is called a *compound pendulum*. The ideal body concentrated at the centre of oscillation, suspended from the centre of suspension by a string without weight, is called a *simple pendulum*. This equivalent simple pendulum has the same weight as the given body, and also the same moment of inertia, referred to an axis passing through the point of suspension, and it oscillates in the same time.

The ordinary pendulum of a given length vibrates in equal times when the angle of the vibrations does not exceed 4 or 5 degrees, that is,  $2^\circ$  or  $2\frac{1}{2}^\circ$  each side of the vertical. This property of a pendulum is called its isochronism.

The time of vibration of a pendulum varies directly as the square root of the length, and inversely as the square root of the acceleration due to gravity at the given latitude and elevation above the earth's surface.

If  $T$  = the time of vibration,  $l$  = length of the simple pendulum,  $g$  = acceleration = 32.16,  $T = \pi \sqrt{\frac{l}{g}}$ ; since  $\pi$  is constant,  $T \propto \frac{\sqrt{l}}{\sqrt{g}}$ . At a given location  $g$  is constant and  $T \propto \sqrt{l}$ . If  $l$  be constant, then for any location  $T \propto \frac{1}{\sqrt{g}}$ . If  $T$  be constant,  $gT^2 = \pi^2 l$ ;  $l \propto g$ ;  $g = \frac{\pi^2 l}{T^2}$ . From this equation

the force of gravity at any place may be determined if the length of the simple pendulum, vibrating seconds, at that place is known. At New York this length is 39.1017 inches = 3.2585 ft., whence  $g = 32.16$  ft. At London the length is 39.1393 inches. At the equator 39.0152 or 39.0168 inches, according to different authorities.

Time of vibration of a pendulum of a given length at New York

$$= t = \sqrt{\frac{l}{39.1017}} = \frac{\sqrt{l}}{6.253}$$

$t$  being in seconds and  $l$  in inches. Length of a pendulum having a given time of vibration,  $l = t^2 \times 39.1017$  inches.

The time of vibration of a pendulum may be varied by the addition of a weight at a point above the centre of suspension, which counteracts the lower weight, and lengthens the period of vibration. By varying the height of the upper weight the time is varied.

To find the weight of the upper bob of a compound pendulum, vibrating seconds, when the weight of the lower bob, and the distances of the weights from the point of suspension are given:

$$w = W \frac{(39.1 \times D) - D^2}{(39.1 \times d) + d^2}$$

$W$  = the weight of the lower bob,  $w$  = the weight of the upper bob;  $D$  = the distance of the lower bob and  $d$  = the distance of the upper bob from the point of suspension, in inches.

Thus, by means of a second bob, short pendulums may be constructed to vibrate as slowly as longer pendulums.

By increasing  $w$  or  $d$  until the lower weight is entirely counterbalanced, the time of vibration may be made infinite.

**Conical Pendulum.**—A weight suspended by a cord and revolving at a uniform speed in the circumference of a circular horizontal plane whose radius is  $r$ , the distance of the plane below the point of suspension being  $h$ , is held in equilibrium by three forces—the tension in the cord, the centrifugal force, which tends to increase the radius  $r$ , and the force of gravity acting downward. If  $v$  = the velocity in feet per second, the centre of gravity of the weight, as it describes the circumference,  $g = 32.16$ , and  $r$  and  $h$  are taken in feet, the time in seconds of performing one revolution is

$$t = \frac{2\pi r}{v} = 2\pi \sqrt{\frac{h}{g}}; \quad h = \frac{gt^2}{4\pi^2} = .8146t^2.$$

If  $t = 1$  second,  $h = .8146$  foot = 9.775 inches.

The principle of the conical pendulum is used in the ordinary fly-ball governor for steam-engines. (See Governors.)

**CENTRIFUGAL FORCE.**

A body revolving in a curved path of radius =  $R$  in feet exerts a force, called centrifugal force,  $F$ , upon the arm or cord which restrains it from moving in a straight line, or “flying off at a tangent.” If  $W$  = weight of the body in pounds,  $N$  = number of revolutions per minute,  $v$  = linear velocity of the centre of gravity of the body, in feet per second,  $g = 32.16$ , then

$$v = \frac{2\pi RN}{60}; \quad F = \frac{Wv^2}{gR} = \frac{Wv^2}{32.16R} = \frac{W4\pi^2 RN^2}{3600g} = \frac{WRN^2}{2933} = .0003410WRN^2 \text{ lbs.}$$

If  $n$  = number of revolutions per second,  $F = 1.2276WRn^2$ .

(For centrifugal force in fly-wheels, see Fly-wheels.)

**VELOCITY, ACCELERATION, FALLING BODIES.**

**Velocity** is the rate of motion, or the distance passed over by a body in a given time.

If  $s$  = space in feet passed over in  $t$  seconds, and  $v$  = velocity in feet per second, if the velocity is uniform,

$$v = \frac{s}{t}; \quad s = vt; \quad t = \frac{s}{v}.$$

If the velocity varies uniformly, the mean velocity  $v_0 = \frac{v_1 + v_2}{2}$ , in which  $v_1$  is the velocity at the beginning and  $v_2$  the velocity at the end of the time  $t$ .

$$s = \frac{v_1 + v_2}{2}t. \dots \dots \dots (1)$$

**Acceleration** is the change in velocity which takes place in a unit of time. Unit of acceleration =  $a = 1$  foot per second in one second. For uniformly varying velocity, the acceleration is a constant quantity, and

$$a = \frac{v_2 - v_1}{t}; \quad v_2 = v_1 + at; \quad v_1 = v_2 - at; \quad t = \frac{v_2 - v_1}{a}. \dots \dots (2)$$

If the body start from rest,  $v_1 = 0$ ; then

$$v_0 = \frac{v^2}{2}; \quad v_2 = 2v_0; \quad a = \frac{v_2}{t}; \quad v_2 = at; \quad v_2 - at = 0; \quad t = \frac{v_2}{a}.$$

Combining (1) and (2), we have

$$s = \frac{v_2^2 - v_1^2}{2a}; \quad s = v_1t + \frac{at^2}{2}; \quad s = v_2t - \frac{at^2}{2}.$$

If  $v_1 = 0$ ,  $s = \frac{v_2^2}{2a}$ .

**Retarded Motion.**—If the body start with a velocity  $v_1$  and come to rest,  $v_2 = 0$ ; then  $s = \frac{v_1^2}{2a}$ .

In any case, if the change in velocity is  $v$ ,

$$s = \frac{v}{2}t; \quad s = \frac{v^2}{2a}; \quad s = \frac{a}{2}t^2.$$

For a body starting from or ending at rest, we have the equations

$$v = at; \quad s = \frac{v}{2}t; \quad s = \frac{at^2}{2}; \quad v^2 = 2as.$$

**Falling Bodies.**—In the case of falling bodies the acceleration due to gravity is 32.16 feet per second in one second, =  $g$ . Then if  $v$  = velocity acquired at the end of  $t$  seconds, or final velocity, and  $h$  = height or space in feet passed over in the same time,

$$v = gt = 32.16t = \sqrt{2gh} = 8.02 \sqrt{h} = \frac{2h}{t};$$

$$h = \frac{gt^2}{2} = 16.08t^2 = \frac{v^2}{2g} = \frac{v^2}{64.32} = \frac{vt}{2};$$

$$t = \frac{v}{g} = \frac{v}{32.16} = \sqrt{\frac{2h}{g}} = \frac{\sqrt{h}}{4.01} = \frac{2h}{v};$$

$$u = \text{space fallen through in the } T\text{th second} = g(T - \frac{1}{2}).$$

From the above formula for falling bodies we obtain the following :

During the first second the body starting from a state of rest (resistance of the air neglected) falls  $g \div 2 = 16.08$  feet ; the acquired velocity is  $g = 32.16$  ft. per sec. ; the distance fallen in two seconds is  $h = \frac{gt^2}{2} = 16.08 \times 4 = 64.32$  ft. ; and the acquired velocity is  $v = gt = 64.32$  ft. The acceleration, or increase of velocity in each second, is constant, and is 32.16 ft. per sec. Solving the equations for different times, we find for

Seconds, $t$ .....	..	1	2	3	4	5	6
Acceleration, $g$ .....	32.16	×	1	1	1	1	1
Velocity acquired at end of time, $v$ ...	32.16	×	1	2	3	4	5
Height of fall in each second, $u$ ... ..	$\frac{32.16}{2}$	×	1	3	5	7	9
Total height of fall, $h$ .....	$\frac{32.16}{2}$	×	1	4	9	16	25
							36

**Value of  $g$ .**—The value of  $g$  increases with the latitude, and decreases with the elevation. At the latitude of Philadelphia,  $40^\circ$ , its value is 32.16. At the sea-level, Everett gives  $g = 32.173 - .082 \cos 2 \text{ lat.} - .000003 \text{ height in feet.}$  At Paris, lat.  $48^\circ 50' \text{ N.}$ ,  $g = 980.87 \text{ cm.} = 32.181 \text{ ft.}$

Values of  $\sqrt{2g}$ , calculated by an equation given by C. S. Pierce, are given in a table in Smith's Hydraulics, from which we take the following :

Latitude.....	$0^\circ$	$10^\circ$	$20^\circ$	$30^\circ$	$40^\circ$	$50^\circ$	$60^\circ$
Value of $\sqrt{2g}$ ..	8.0112	8.0118	8.0137	8.0165	8.0199	8.0235	8.0269

The value of  $\sqrt{2g}$  decreases about .0004 for every 1000 feet increase in elevation above the sea-level.

For all ordinary calculations for the United States,  $g$  is generally taken at 32.16, and  $\sqrt{2g}$  at 8.02. In England  $g = 32.2$ ,  $\sqrt{2g} = 8.025$ . Practical limiting values of  $g$  for the United States, according to Pierce, are :

Latitude $49^\circ$ at sea-level .....	$g = 32.186$
" $25^\circ$ 10.000 feet above the sea.....	$g = 32.08'$

Fig. 95 represents graphically the velocity, space, etc., of a body falling for six seconds. The vertical line at the left is the time in seconds, the horizontal lines represent the acquired velocities at the end of each second =  $32.16t$ . The area of the small triangle at the top represents the height fallen through in the first second =  $\frac{1}{2}g = 16.08$  feet, and each of the other triangles is an equal space. The number of triangles between each pair of horizontal lines represents the height of fall in each second, and the number of triangles between any horizontal line and the top is the total height fallen during the time. The figures under  $h$ ,  $u$ , and  $v$  adjoining the cut are to be multiplied by 16.08 to obtain the actual velocities and heights for the given times.

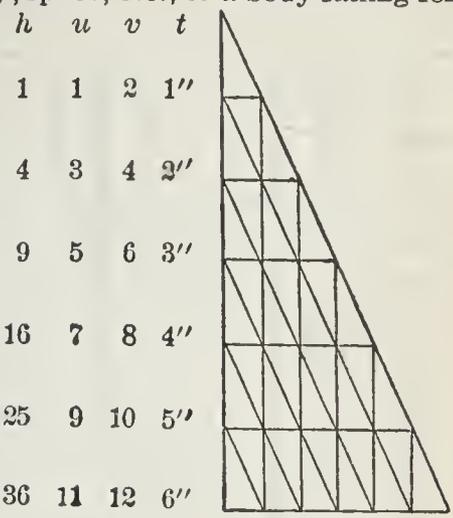

FIG. 95.

**Angular and Linear Velocity** of a Turning Body.—Let  $r$  = radius of a turning body in feet,  $n$  = number of revolutions per minute,  $v$  = linear velocity of a point on the circumference in feet per second, and  $60v$  = velocity in feet per minute.

$$v = \frac{2\pi rn}{60}, \quad 60v = 2\pi rn.$$

Angular velocity is a term used to denote the angle through which any radius of a body turns in a second, or the rate at which any point in it having a radius equal to unity is moving, expressed in feet per second. The unit of angular velocity is the angle which at a distance = radius from the centre is subtended by an arc equal to the radius. This unit angle =  $\frac{180}{\pi}$  degrees =  $57.3^\circ$ .  $2\pi \times 57.3^\circ = 360^\circ$ , or the circumference. If  $A$  = angular velocity,  $v = Ar$ ,  $A = \frac{v}{r} = \frac{2\pi n}{60}$ . The unit angle  $\frac{180}{\pi}$  is called a *radian*.

**Parallelogram of Velocities.**—The principle of the composition and resolution of forces may also be applied to velocities or to distances moved in given intervals of time. Referring to Fig. 88, page 416, if a body at *O* has a force applied to it which acting alone would give it a velocity represented by *OQ* per second, and at the same time it is acted on by

another force which acting alone would give it a velocity  $OP$  per second, the result of the two forces acting together for one second will carry it to  $R$ ,  $OR$  being the diagonal of the parallelogram of  $OQ$  and  $OP$ , and the resultant velocity. If the two component velocities are uniform, the resultant will be uniform and the line  $OR$  will be a straight line; but if either resultant velocities, also the path traversed by a body acted on by two forces, one of which would carry it at a uniform velocity over the intervals 1, 2, 3,  $B$ , and the other of which would carry it by an accelerated motion over the intervals  $a$ ,  $b$ ,  $c$ ,  $D$  in the same times. At the end of the respective intervals the body will be found at  $C_1, C_2, C_3, C$ , and the mean velocity during each interval is represented by the distances between these points. Such a curved path is traversed by a shot, the impelling force from the gun giving it a uniform velocity in the direction the gun is aimed, and gravity giving it an accelerated velocity downward. *The path of a projectile is a parabola.* The distance it will travel is greatest when its initial direction is at an angle  $45^\circ$  above the horizontal.

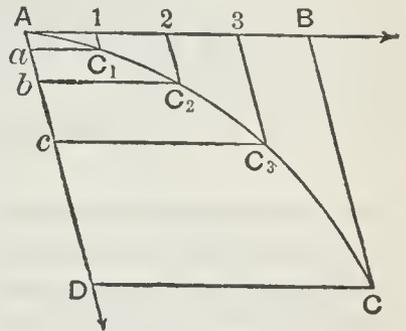

FIG. 96.

**Mass—Force of Acceleration.**—*The mass* of a body, or the quantity of matter it contains, is a constant quantity, while the weight varies according to the variation in the force of gravity at different places. If  $g$  = the acceleration due to gravity, and  $w$  = weight, then the mass  $m = \frac{w}{g}$ ,  $w = mg$ . Weight here means the resultant of the force of gravity on the particles of a body, such as may be measured by a spring-balance, or by the extension or deflection of a rod of metal loaded with the given weight.

Force has been defined as that which causes, or tends to cause, or to destroy, motion. It may also be defined (Kennedy's *Mechanics of Machinery*) as the cause of acceleration; and the unit of force as the force required to produce unit acceleration in a unit of free mass.

Force equals the product of the mass by the acceleration, or  $f = ma$ .

Also, if  $v$  = the velocity acquired in the time  $t$ ,  $ft = mv$ ;  $f = mv \div t$ ; the acceleration being uniform.

The force required to produce an acceleration of  $g$  (that is, 32.16 ft. per sec.) in one second is  $f = mg = \frac{w}{g}g = w$ , or the weight of the body. Also,

$f = ma = m \frac{v_2 - v_1}{t}$ , in which  $v_2$  is the velocity at the end, and  $v_1$  the

velocity at the beginning of the time  $t$ , and  $f = mg = \frac{w}{g} \frac{(v_2 - v_1)}{t} = \frac{w}{g} a$ ;

$\frac{f}{w} = \frac{a}{g}$ ; or, the force required to give any acceleration to a body is to the weight of the body as that acceleration is to the acceleration produced by gravity. (The weight  $w$  is the weight where  $g$  is measured.)

**EXAMPLE.**—Tension in a cord lifting a weight. A weight of 100 lbs. is lifted vertically by a cord a distance of 80 feet in 4 seconds, the velocity uniformly increasing from 0 to the end of the time. What tension must be maintained in the cord? Mean velocity =  $v_0 = 20$  ft. per sec.; final velocity =  $v_2 = 2v_0 = 40$ ; acceleration  $a = \frac{v_2}{t} = \frac{40}{4} = 10$ . Force  $f = ma = \frac{wa}{g} = \frac{100}{32.16} \times 10 = 31.1$  lbs. This is the force required to produce the acceleration only; to it must be added the force required to lift the weight without acceleration, or 100 lbs., making a total of 131.1 lbs.

*The Resistance to Acceleration* is the same as the force required to produce the acceleration =  $\frac{w}{g} \frac{(v_2 - v_1)}{t}$ .

**Formulae for Accelerated Motion.**—For cases of uniformly accelerated motion other than those of falling bodies, we have the formulæ already given,  $f = \frac{w}{g} a$ , =  $\frac{w}{g} \frac{v_2 - v_1}{t}$ . If the body starts from rest,  $v_1 = 0$ ,  $v_2$

$= v$ , and  $f = \frac{wv}{t}$ ,  $fgt = wv$ . We also have  $s = \frac{vt}{2}$ . Transforming and substituting for  $g$  its value 32.16, we obtain

$$f = \frac{wv^2}{64.32s} = \frac{wv}{32.16t} = \frac{ws}{16.08t^2}; \quad w = \frac{32.16ft}{v} = \frac{64.32fs}{v^2};$$

$$s = \frac{wv^2}{64.32f} = \frac{16.08ft^2}{w} = \frac{vt}{2}; \quad v = 8.02 \sqrt{\frac{fs}{w}} = \frac{32.16ft}{w};$$

$$t = \frac{wv}{32.16f} = \frac{1}{4.01} \sqrt{\frac{ws}{f}}$$

For any change in velocity  $f = w \left( \frac{v_2^2 - v_1^2}{64.32s} \right)$ .

(See also Work of Acceleration, under Work.)

**Motion on Inclined Planes.**—The velocity acquired by a body descending an inclined plane by the force of gravity (friction neglected) is equal to that acquired by a body falling freely from the height of the plane.

The times of descent down different inclined planes of the same height vary as the length of the planes.

The rules for uniformly accelerated motion apply to inclined planes. If  $a$  is the angle of the plane with the horizontal,  $\sin a =$  the ratio of the height to the length  $= \frac{h}{l}$ , and the constant accelerating force is  $g \sin a$ . The final velocity at the end of  $t$  seconds is  $v = gt \sin a$ . The distance passed over in  $t$  seconds is  $l = \frac{1}{2} gt^2 \sin a$ . The time of descent is

$$t = \sqrt{\frac{2l}{g \sin a}} = \frac{l}{4.01 \sqrt{h}}$$

### MOMENTUM, VIS-VIVA.

**Momentum**, or quantity of motion in a body, is the product of the mass by the velocity at any instant  $= mv = \frac{w}{g}v$ .

Since the moving force  $=$  product of mass by acceleration,  $f = ma$ ; and if the velocity acquired in  $t$  seconds  $= v$ , or  $a = \frac{v}{t}$ ,  $f = \frac{mv}{t}$ ;  $ft = mv$ ; that is, the product of a constant force into the time in which it acts equals numerically the momentum.

Since  $ft = mv$ , if  $t = 1$  second  $mv = f$ , whence momentum might be defined as numerically equivalent to the number of pounds of force that will stop a moving body in 1 second, or the number of pounds of force which acting during 1 second will give it the given velocity.

**Vis-viva**, or living force, is a term used by early writers on Mechanics to denote the energy stored in a moving body. Some defined it as the product of the mass into the square of the velocity,  $mv^2 = \frac{w}{g}v^2$  others as one half of this quantity or  $\frac{1}{2}mv^2$ , or the same as what is now known as energy. The term is now practically obsolete, its place being taken by the word energy.

### WORK, ENERGY, POWER.

**Work** is the overcoming of resistance through a certain distance. It is measured by the product of the resistance into the space through which it is overcome. It is also measured by the product of the moving force into the distance through which the force acts in overcoming the resistance. Thus in lifting a body from the earth against the attraction of gravity, the resistance is the weight of the body, and the product of this weight into the height the body is lifted is the work done.

**The Unit of Work**, in British measures, is the *foot-pound*, or the amount of work done in overcoming a pressure or weight equal to one pound through one foot of space.

The work performed by a piston in driving a fluid before it, or by a fluid in driving a piston before it, may be expressed in either of the following ways:

$$\begin{aligned} & \text{Resistance} \times \text{distance traversed} \\ & = \text{intensity of pressure} \times \text{area} \times \text{distance traversed}; \\ & = \text{intensity of pressure} \times \text{volume traversed.} \end{aligned}$$

The work performed in lifting a body is the product of the weight of the body into the height through which its centre of gravity is lifted.

If a machine lifts the centres of gravity of several bodies at once to heights either the same or different, the whole quantity of work performed in so doing is the sum of the several products of the weights and heights; but that quantity can also be computed by multiplying the sum of all the weights into the height through which their common centre of gravity is lifted. (Rankine.)

**Power** is the rate at which work is done, and is expressed by the quotient of the work divided by the time in which it is done, or by units of work per second, per minute, etc., as foot-pounds per second. The most common unit of power is the *horse-power*, established by James Watt as the power of a strong London draught-horse to do work during a short interval, and used by him to measure the power of his steam-engines. This unit is 33,000 foot-pounds per minute = 550 foot-pounds per second = 1,980,000 foot-pounds per hour.

### Expressions for Force, Work, Power, etc.

The fundamental conceptions in Dynamics are:

**Mass, Force, Time, Space**, represented by the letters  $M, F, T, S$ .

**Mass** = weight  $\div g$ . If the weight of a body is determined by a spring balance standardized at London it will vary with the latitude, and the value of  $g$  to be taken in order to find the mass is that of the latitude where the weighing is done. If the weight is determined by a balance or by a platform scale, as is customary in engineering and in commerce, the London value of  $g = 32.2$ , is to be taken.

**Velocity** = space divided by time,  $V = S \div T$ , if  $V$  be uniform.

**Work** = force multiplied by space =  $FS = \frac{1}{2}MV^2 = FVT$ . ( $V$  uniform.)

**Power** = rate of work = work divided by time =  $FS \div T = P =$  product of force into velocity =  $FV$ .

Power exerted for a certain time produces work;  $PT = FS = FVT$ .

**Effort** is a force which acts on a body in the direction of its motion.

**Resistance** is that which is opposed to a moving force. It is equal and opposite force.

**Horse-power Hours**, an expression for work measured as the product of a power into the time during which it acts =  $PT$ . Sometimes it is the summation of a variable power for a given time, or the average power multiplied by the time.

**Energy**, or stored work, is the capacity for performing work. It is measured by the same unit as work, that is, in foot-pounds. It may be either *potential*, as in the case of a body of water stored in a reservoir, capable of doing work by means of a water-wheel, or *actual*, sometimes called *kinetic*, which is the energy of a moving body. Potential energy is measured by the product of the weight of the stored body into the distance through which it is capable of acting, or by the product of the pressure it exerts into the distance through which that pressure is capable of acting. Potential energy may also exist as stored heat, or as stored chemical energy, as in fuel, gunpowder, etc., or as electrical energy, the measure of these energies being the amount of work that they are capable of performing. Actual energy of a moving body is the work which it is capable of performing against a retarding resistance before being brought to rest, and is equal to the work which must be done upon it to bring it from a state of rest to its actual velocity.

The measure of actual energy is the product of the weight of the body into the height from which it must fall to acquire its actual velocity. If  $v =$  the velocity in feet per second, according to the principle of falling bodies,

$$h, \text{ the height due to the velocity} = \frac{v^2}{2g}, \text{ and if } w = \text{the weight, the energy} =$$

$$\frac{1}{2}mv^2 = wv^2 \div 2g = wh. \text{ Since energy is the capacity for performing work, the units of work and energy are equivalent, or } FS = \frac{1}{2}mv^2 = wh.$$

**Energy exerted** = work done.

The actual energy of a rotating body whose angular velocity is  $A$  and moment of inertia  $\Sigma wr^2 = I$  is  $\frac{A^2 I}{2g}$ , that is, the product of the moment of inertia into the height due to the velocity,  $A$ , of a point whose distance from the axis of rotation is unity; or it is equal to  $\frac{wv^2}{2g}$ , in which  $w$  is the weight of the body and  $v$  is the velocity of the centre of gyration.

**Work of Acceleration.**—The work done in giving acceleration to a body is equal to the product of the force producing the acceleration, or of the resistance to acceleration, into the distance moved in a given time. This force, as already stated equals the product of the mass into the acceleration,

or  $f = ma = \frac{w}{g} \frac{v_2 - v_1}{t}$ . If the distance traversed in the time  $t = s$ , then

$$\text{work} = fs = \frac{w}{g} \frac{v_2 - v_1}{t} s.$$

EXAMPLE.—What work is required to move a body weighing 100 lbs. horizontally a distance of 80 ft. in 4 seconds, the velocity uniformly increasing, friction neglected?

Mean velocity  $v_0 = 20$  ft. per second; final velocity  $= v_2 = 2v_0 = 40$ ; initial velocity  $v_1 = 0$ ; acceleration,  $\alpha = \frac{v_2 - v_1}{t} = \frac{40}{4} = 10$ ; force  $= \frac{w}{g} a = \frac{100}{32.16} \times 10 = 31.1$  lbs.; distance 80 ft.; work  $= fs = 31.1 \times 80 = 2488$  foot-pounds.

The energy stored in the body moving at the final velocity of 40 ft. per second is

$$\frac{1}{2}mv^2 = \frac{1}{2} \frac{w}{g} v^2 = \frac{100 \times 40^2}{2 \times 32.16} = 2488 \text{ foot-pounds,}$$

which equals the work of acceleration,

$$fs = \frac{w}{g} \frac{v_2}{t} s = \frac{w}{g} \frac{v_2}{t} \frac{v_2 t}{2} = \frac{1}{2} \frac{w}{g} v_2^2.$$

If a body of the weight  $W$  falls from a height  $H$ , the work of acceleration is simply  $WH$ , or the same as the work required to raise the body to the same height.

**Work of Accelerated Rotation.**—Let  $A$  = angular velocity of a solid body rotating about an axis, that is, the velocity of a particle whose radius is unity. Then the velocity of a particle whose radius is  $r$  is  $v = Ar$ . If the angular velocity is accelerated from  $A_1$  to  $A_2$ , the increase of the velocity of the particle is  $v_2 - v_1 = r(A_2 - A_1)$ , and the work of accelerating it is

$$\frac{w}{g} \times \frac{v_2^2 - v_1^2}{2} = \frac{wr^2}{g} \cdot \frac{A_2^2 - A_1^2}{2},$$

in which  $w$  is the weight of the particle.

The work of acceleration of the whole body is

$$\Sigma \left\{ \frac{w}{g} \times \frac{v_2^2 - v_1^2}{2} \right\} = \frac{A_2^2 - A_1^2}{2g} \times \Sigma wr^2.$$

The term  $\Sigma wr^2$  is the moment of inertia of the body.

**“Force of the Blow” of a Steam Hammer or Other Falling Weight.**—The question is often asked: “With what force does a falling hammer strike?” The question cannot be answered directly, and it is based upon a misconception or ignorance of fundamental mechanical laws. The energy, or capacity of doing work, of a body raised to a given height and let fall cannot be expressed in pounds, simply, but only in foot-pounds, which is the product of the weight into the height through which it falls, or the product of its weight  $\div 64.32$  into the square of the velocity, in feet per second, which it acquires after falling through the given height. If  $F$  = weight of the body,  $M$  its mass,  $g$  the acceleration due to gravity,  $S$  the height of fall, and  $v$  the velocity at the end of the fall, the energy in the body just before striking, is  $FS = \frac{1}{2}Mv^2 = Wv^2 \div 2g = Wv^2 \div 64.32$ , which is the general equation of energy of a moving body. Just as the energy of the body is a product of a force into a distance, so the work it does when it strikes is not the manifestation of a force, which can be expressed simply in pounds, but it is the overcoming of a resistance through a certain distance, which is expressed as the product of the average resist-

ance into the distance through which it is exerted. If a hammer weighing 100 lbs. falls 10 ft., its energy is 1000 foot-pounds. Before being brought to rest it must do 1000 foot-pounds of work against one or more resistances. These are of various kinds, such as that due to motion imparted to the body struck, penetration against friction, or against resistance to shearing or other deformation, and crushing and heating of both the falling body and the body struck. The distance through which these resisting forces act is generally indeterminate, and therefore the average of the resisting forces, which themselves generally vary with the distance, is also indeterminate.

**Impact of Bodies.**—If two inelastic bodies collide, they will move on together as one mass, with a common velocity. The momentum of the combined mass is equal to the sum of the momenta of the two bodies before impact. If  $m_1$  and  $m_2$  are the masses of the two bodies and  $v_1$  and  $v_2$  their respective velocities before impact, and  $v$  their common velocity after impact,  $(m_1 + m_2)v = m_1v_1 + m_2v_2$ ,

$$v = \frac{m_1v_1 + m_2v_2}{m_1 + m_2}.*$$

If the bodies move in opposite directions  $v = \frac{m_1v_1 - m_2v_2}{m_1 + m_2}$ , or, the velocity of two inelastic bodies after impact is equal to the algebraic sum of their momenta before impact, divided by the sum of their masses.

If two inelastic bodies of equal momenta impinge directly upon one another from opposite directions they will be brought to rest.

**Impact of Inelastic Bodies Causes a Loss of Energy**, and this loss is equal to the sum of the energies due to the velocities lost and gained by the bodies, respectively.

$$\frac{1}{2}m_1v_1^2 + \frac{1}{2}m_2v_2^2 - \frac{1}{2}(m_1 + m_2)v^2 = \frac{1}{2}m_1(v_1 - v)^2 + \frac{1}{2}m_2(v_2 - v)^2.$$

In which  $v_1 - v$  is the velocity lost by  $m_1$  and  $v - v_2$  the velocity gained by  $m_2$ .

*Example*—Let  $m_1 = 10$ ,  $m_2 = 8$ ,  $v_1 = 12$ ,  $v_2 = 15$ .

If the bodies collide they will come to rest, for  $v = \frac{10 \times 12 - 8 \times 15}{10 + 8} = 0$ .

The energy loss is

$$\frac{1}{2}10 \times 144 + \frac{1}{2}8 \times 225 - \frac{1}{2}18 \times 0 = \frac{1}{2}10(12 - 0)^2 + \frac{1}{2}8(15 - 0)^2 = 1620 \text{ ft. lbs.}$$

What becomes of the energy lost? Ans. It is used doing internal work on the bodies themselves, changing their shape and heating them.

*For imperfectly elastic bodies*, let  $e$  = the elasticity, that is, the ratio which the force of restitution, or the internal force tending to restore the shape of a body after it has been compressed, bears to the force of compression; and let  $m_1$  and  $m_2$  be the masses,  $v_1$  and  $v_2$  their velocities before impact, and  $v_1'v_2'$  their velocities after impact: then

$$v_1' = \frac{m_1v_1 + m_2v_2}{m_1 + m_2} - \frac{m_2e(v_1 - v_2)}{m_1 + m_2};$$

$$v_2' = \frac{m_1v_1 + m_2v_2}{m_1 + m_2} + \frac{m_1e(v_1 - v_2)}{m_1 + m_2}.$$

If the bodies are perfectly elastic, their relative velocities before and after impact are the same. That is:  $v_1' - v_2' = v_2 - v_1$ .

In the impact of bodies, the sum of their momenta after impact is the same as the sum of their momenta before impact.

$$m_1v_1' + m_2v_2' = m_1v_1 + m_2v_2.$$

For demonstration of these and other laws of impact, see Smith's Mechanics; also, Weisbach's Mechanics.

**Energy of Recoil of Guns.**—(*Eng'g*, Jan. 25, 1884, p. 72.)

Let  $W$  = the weight of the gun and carriage;

$V$  = the maximum velocity of recoil;

$w$  = the weight of the projectile;

$v$  = the muzzle velocity of the projectile.

Then, since the momentum of the gun and carriage is equal to the momentum of the projectile, we have  $WV = wv$ , or  $V = wv \div W$ .

\* The statement by Prof. W. D. Marks, in Nystrom's Mechanics, 20th edition, p. 454, that this formula is in error is itself erroneous.

Taking the case of a 10-inch gun firing a 400-lb. projectile with a muzzle velocity of 1400 feet per second, the weight of the gun and carriage being 23 tons = 49,280 lbs., we find the velocity of recoil =

$$V = \frac{1400 \times 400}{49,280} = 11 \text{ feet per second.}$$

Now the energy of a body in motion is  $WV^2 \div 2g$ .

Therefore the energy of recoil =  $\frac{49,280 \times 11^2}{2 \times 32.2} = 92,593$  foot-pounds.

The energy of the projectile is  $\frac{400 \times 1400^2}{2 \times 32.2} = 12,173,913$  foot-pounds.

**Conservation of Energy.**—No form of energy can ever be produced except by the expenditure of some other form, nor annihilated except by being reproduced in another form. Consequently the sum total of energy in the universe, like the sum total of matter, must always remain the same. (S. Newcomb.) Energy can never be destroyed or lost; it can be transformed, can be transferred from one body to another, but no matter what transformations are undergone, when the total effects of the exertion of a given amount of energy are summed up the result will be exactly equal to the amount originally expended from the source. This law is called the Conservation of Energy. (Cotterill and Slade.)

A heavy body sustained at an elevated position has potential energy. When it falls, just before it reaches the earth's surface it has actual or kinetic energy, due to its velocity. When it strikes it may penetrate the earth a certain distance or may be crushed. In either case friction results by which the energy is converted into heat, which is gradually radiated into the earth or into the atmosphere, or both. Mechanical energy and heat are mutually convertible. Electric energy is also convertible into heat or mechanical energy, and either kind of energy may be converted into the other.

**Sources of Energy.**—The principal sources of energy on the earth's surface are the muscular energy of men and animals, the energy of the wind, of flowing water, and of fuel. These sources derive their energy from the rays of the sun. Under the influence of the sun's rays vegetation grows and wood is formed. The wood may be used as fuel under a steam boiler, its carbon being burned to carbonic acid. Three tenths of its heat energy escapes in the chimney and by radiation, and seven tenths appears as potential energy in the steam. In the steam-engine, of this seven tenths six parts are dissipated in heating the condensing water and are wasted; the remaining one tenth of the original heat energy of the wood is converted into mechanical work in the steam-engine, which may be used to drive machinery. This work is finally, by friction of various kinds, or possibly after transformation into electric currents, transformed into heat, which is radiated into the atmosphere, increasing its temperature. Thus all the potential heat energy of the wood is, after various transformations, converted into heat, which, mingling with the store of heat in the atmosphere, apparently is lost. But the carbonic acid generated by the combustion of the wood is, again, under the influence of the sun's rays, absorbed by vegetation, and more wood may thus be formed having potential energy equal to the original.

**Perpetual Motion.**—The law of the conservation of energy, than which no law of mechanics is more firmly established, is an absolute barrier to all schemes for obtaining by mechanical means what is called "perpetual motion," or a machine which will do an amount of work greater than the equivalent of the energy, whether of heat, of chemical combination, of electricity, or mechanical energy, that is put into it. Such a result would be the creation of an additional store of energy in the universe, which is not possible by any human agency.

**The Efficiency of a Machine** is a fraction expressing the ratio of the useful work to the whole work performed, which is equal to the energy expended. The limit to the efficiency of a machine is unity, denoting the efficiency of a perfect machine in which no work is lost. The difference between the energy expended and the useful work done, or the loss, is usually expended either in overcoming friction or in doing work on bodies surrounding the machine from which no useful work is received. Thus in an engine propelling a vessel part of the energy exerted in the cylinder

does the useful work of giving motion to the vessel, and the remainder is spent in overcoming the friction of the machinery and in making currents and eddies in the surrounding water.

**ANIMAL POWER.**

**Work of a Man against Known Resistances. (Rankine.)**

Kind of Exertion.	$R$ , lbs.	$V$ , ft. per sec.	$\frac{T''}{3600}$ (hours per day).	$RV$ , ft.-lbs. per sec.	$RVT$ , ft.-lbs. per day.
1. Raising his own weight up stair or ladder .....	143	0.5	8	72.5	2,088,000
2. Hauling up weights with rope, and lowering the rope unloaded.....	40	0.75	6	30	648,000
3. Lifting weights by hand.....	44	0.55	6	24.2	522,720
4. Carrying weights up-stairs and returning unloaded....	143	0.13	6	18.5	399,600
5. Shovelling up earth to a height of 5 ft. 3 in.....	6	1.3	10	7.8	280,800
6. Wheeling earth in barrow up slope of 1 in 12, $\frac{1}{2}$ horiz. veloc. 0.9 ft. per sec. and returning unloaded.....	132	0.075	10	9.9	356,400
7. Pushing or pulling horizontally (capstan or oar).....	26.5	2.0	8	53	1,526,400
8. Turning a crank or winch ...	12.5	5.0	?	62.5	.....
	18.0	2.5	8	45	1,296,000

	126	11.7	.....	1474.2	.....
	0	23.1	.....	0	.....

EXPLANATION.— $L$ , load;  $V$ , effective velocity, computed as before;  $T''$ , time of working, in seconds per day;  $T'' \div 3600$ , same time in hours per day;  $LV$ , transport per second, in lbs. conveyed one foot;  $LVT$ , daily transport.

In the first line only of each of the two tables above is the weight of the man taken into account in computing the work done.

Clark says that the average net daily work of an ordinary laborer at a pump, a winch, or a crane may be taken at 3300 foot-pounds per minute, or one-tenth of a horse-power, for 8 hours a day; but for shorter periods from four to five times this rate may be exerted.

Mr. Glynn says that a man may exert a force of 25 lbs. at the handle of a crane for short periods; but that for continuous work a force of 15 lbs. is all that should be assumed, moving through 220 feet per minute.

**Man-wheel.**—Fig. 97 is a sketch of a very efficient man-power hoisting-machine which the author saw in Berne, Switzerland, in 1889. The face of the wheel was wide enough for three men to walk abreast, so that nine men could work in it at one time.

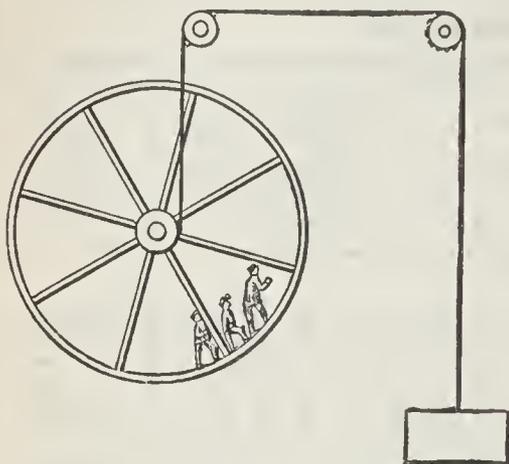

FIG. 97.

**Work of a Horse against a Known Resistance.** (Rankine.)

Kind of Exertion,	<i>R.</i>	<i>V.</i>	$\frac{T.}{3600}$	<i>RV.</i>	<i>RVT.</i>					
1. Cantering and trotting, drawing a light railway carriage (thoroughbred).....	$\left. \begin{array}{l} \text{min. } 22\frac{1}{2} \\ \text{mean } 30\frac{1}{2} \\ \text{max. } 50 \end{array} \right\} 14\frac{2}{3}$	4	4	447½	6,444,000					
2. Horse drawing cart or boat, walking (draught-horse)....						120	3.6	8	432	12,441,600
3. Horse drawing a gin or mill, walking .....						100	3.0	8	300	8,640,000
4. Ditto, trotting .....	66	6.5	4½	429	6,950,000					

EXPLANATION.—*R*, resistance, in lbs.; *V*, velocity, in feet per second;  $T \div 3600$ , hours work per day; *RV*, work per second; *RVT*, work per day.

The average power of a draught-horse, as given in line 2 of the above table, being 432 foot-pounds per second, is  $432/550 = 0.785$  of the conventional value assigned by Watt to the ordinary unit of the rate of work of prime movers. It is the mean of several results of experiments, and may be considered the average of ordinary performance under favorable circumstances.

**Performance of a Horse in Transporting Loads Horizontally.** (Rankine.)

Kind of Exertion.	<i>L.</i>	<i>V.</i>	<i>T.</i>	<i>LV.</i>	<i>LVT.</i>
5. Walking with cart, always loaded.....	1500	3.6	10	5400	194,400,000
6. Trotting, ditto.....	750	7.2	4½	5400	87,480,000
7. Walking with cart, going loaded; returning empty; <i>V</i> , mean velocity.....	1500	2.0	10	3000	108,000,000
8. Carrying burden, walking....	270	3.6	10	972	34,992,000
9. Ditto, trotting .....	180	7.2	7	1296	32,659,200

EXPLANATION.—*L*, load in lbs.; *V*, velocity in feet per second; *T* ÷ 3600, working hours per day; *LV*, transport per second; *LVT*, transport per day.

This table has reference to conveyance on common roads only, and those evidently in bad order as respects the resistance to traction upon them.

**Horse Gin.**—In this machine a horse works less advantageously than in drawing a carriage along a straight track. In order that the best

possible results may be realized with a horse-gin, the diameter of the circular track in which the horse walks should not be less than about forty feet.

**Oxen, Mules, Asses.**—Authorities differ considerably as to the power of these animals. The following may be taken as an approximative comparison between them and draught-horses (Rankine):

*Ox.*—Load, the same as that of average draught-horse; best velocity and work, two thirds of horse.

*Mule.*—Load, one half of that of average draught-horse; best velocity, the same with horse; work one half.

*Ass.*—Load, one quarter that of average draught-horse; best velocity the same; work one quarter.

**Reduction of Draught of Horses by Increase of Grade of Roads.** (*Engineering Record*, Prize Essays on Roads, 1892.)—Experiments on English roads by Gayffier & Parnell:

Calling load that can be drawn on a level 100:

On a rise of. ....	1 in 100.	1 in 50.	1 in 40.	1 in 30.	1 in 26.	1 in 20.	1 in 10.
A horse can draw only	90.	81.	72.	64.	54.	40.	25.

**The Resistance of Carriages on Roads** is (according to Gen. Morin) given approximately by the following empirical formula:

$$R = \frac{W}{r} [a + b(u - 3.28)].$$

In this formula  $R$  = total resistance;  $r$  = radius of wheel in inches;  $W$  = gross load;  $u$  = velocity in feet per second; while  $a$  and  $b$  are constants, whose values are: For good broken-stone road,  $a = .4$  to  $.55$ ,  $b = .024$  to  $.026$ ; for paved roads,  $a = .27$ ,  $b = .0684$ .

Rankine states that on gravel the resistance is about double, and on sand five times, the resistance on good broken-stone roads.

**ELEMENTS OF MACHINES.**

The object of a machine is usually to transform the work or mechanical energy exerted at the point where the machine receives its motion into work at the point where the final resistance is overcome. The specific end may be to change the character or direction of motion, as from circular to rectilinear, or *vice versa*, to change the velocity, or to overcome a great resistance by the application of a moderate force. In all cases the total energy exerted equals the total work done, the latter including the overcoming of all the frictional resistances of the machine as well as the useful work performed. No increase of power can be obtained from any machine, since this is impossible according to the law of conservation of energy. In a frictionless machine the product of the force exerted at the driving-point into the velocity of the driving-point, or the distance it moves in a given interval of time, equals the product of the resistance into the distance through which the resistance is overcome in the same time.

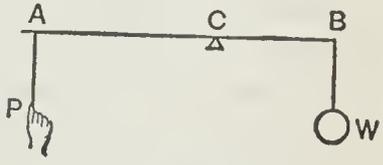

FIG. 98.

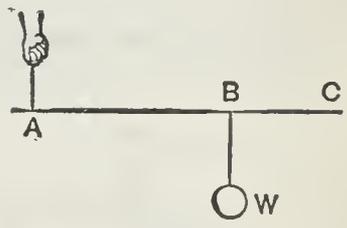

FIG. 99.

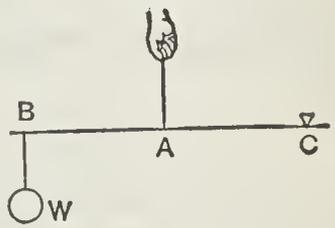

FIG. 100.

The most simple machines, or elementary machines, are reducible to three classes, viz., the Lever, the Cord, and the Inclined Plane.

The first class includes every machine consisting of a solid body capable of revolving on an axis, as the Wheel and Axle.

The second class includes every machine in which force is transmitted by means of flexible threads, ropes, etc., as the Pulley.

The third class includes every machine in which a hard surface inclined to the direction of motion is introduced, as the Wedge and the Screw.

**A Lever** is an inflexible rod capable of motion about a fixed point, called a fulcrum. The rod may be straight or bent at any angle, or curved.

It is generally regarded, at first, as without weight, but its weight may be

considered as another force applied in a vertical direction at its centre of gravity.

The arms of a lever are the portions of it intercepted between the force,  $P$ , and fulcrum,  $C$ , and between the weight,  $W$ , and fulcrum.

Levers are divided into three kinds or orders, according to the relative positions of the applied force, weight, and fulcrum.

In a lever of the first order, the fulcrum lies between the points at which the force and weight act. (Fig. 98.)

In a lever of the second order, the weight acts at a point between the fulcrum and the point of action of the force. (Fig. 99.)

In a lever of the third order, the point of action of the force is between that of the weight and the fulcrum. (Fig. 100.)

In all cases of levers the relation between the force exerted or the pull,  $P$ , and the weight lifted, or resistance overcome,  $W$ , is expressed by the equation  $P \times AC = W \times BC$ , in which  $AC$  is the lever-arm of  $P$ , and  $BC$  is the lever-arm of  $W$ , or moment of the force = the moment of the resistance. (See Moment.)

In cases in which the direction of the force (or of the resistance) is not at right angles to the arm of the lever on which it acts, the "lever-arm" is the length of a perpendicular from the fulcrum to the line of direction of the force (or of the resistance).  $W : P :: AC : BC$ , or, the ratio of the resistance to the applied force is the inverse ratio of their lever-arms. Also, if  $V_w$  is the velocity of  $W$ , and  $V_p$  is the velocity of  $P$ ,  $W : P :: V_p : V_w$ , and  $P \times V_p = W \times V_w$ .

If  $Sp$  is the distance through which the applied force acts, and  $Sw$  is the distance the weight is lifted or through which the resistance is overcome,  $W : P :: Sp : Sw$ ;  $W \times Sw = P \times Sp$ , or the weight into the distance it is lifted equals the force into the distance through which it is exerted.

These equations are general for all classes of machines as well as for levers, it being understood that friction, which in actual machines increases the resistance, is not at present considered.

**The Bent Lever.**—In the bent lever (see Fig. 91, page 416) the lever-arm of the weight  $m$  is  $cf$  instead of  $bf$ . The lever is in equilibrium when  $n \times af = m \times cf$ , but it is to be observed that the action of a bent lever may be very different from that of a straight lever. In the latter, so long as the force and the resistance act in lines parallel to each other, the ratio of the lever-arms remains constant, although the lever itself changes its inclination with the horizontal. In the bent lever, however, this ratio changes: thus, in the cut, if the arm  $bf$  is depressed to a horizontal direction, the distance  $cf$  lengthens while the horizontal projection of  $af$  shortens, the latter becoming zero when the direction of  $af$  becomes vertical. As the arm  $af$  approaches the vertical, the weight  $m$  which may be lifted with a given force  $s$  is very great, but the distance through which it may be lifted is very small. In all cases the ratio of the weight  $m$  to the weight  $n$  is the inverse ratio of the horizontal projection of their respective lever-arms.

**The Moving Strut** (Fig. 101) is similar to the bent lever, except that one of the arms is missing, and that the force and the resistance to be overcome act at the same end of the single arm. The resistance in the case shown in the cut is not the weight  $W$ , but its resistance to being moved,  $R$ , which may be simply that due to its friction on the horizontal plane, or some other opposing force. When the angle between the strut and the horizontal plane changes, the ratio of the resistance to the applied force changes. When the angle becomes very small, a moderate force will overcome a very great resistance, which tends to become infinite as

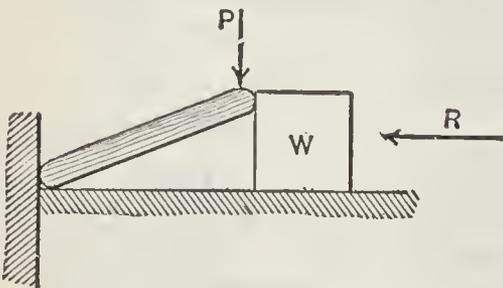

FIG. 101.

the angle approaches zero. If  $a =$  the angle,  $P \times \cos a = R \times \sin a$ . If  $a = 5$  degrees,  $\cos a = .99619$ ,  $\sin a = .08716$ ,  $R = 11.44 P$ .

The stone-crusher (Fig. 102) shows a practical example of the use of two moving struts.

**The Toggle-joint** is an elbow or knee-joint consisting of two bars so connected that they may be brought into a straight line and made to produce great endwise pressure when a force is applied to bring them into this

position. It is a case of two moving struts placed end to end, the moving force being applied at their point of junction, in a direction at right angles to the direction of the resistance, the other end of one of the struts resting against a fixed abutment, and that of the other against the body to be moved. If  $a$  = the angle each strut makes with the straight line joining the points about which their outer ends rotate, the ratio of the resistance to the applied force is  $R : P :: \cos a : 2 \sin a$ ;  $2R \sin a = P \cos a$ . The

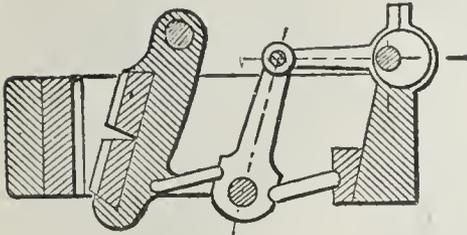

FIG. 102.

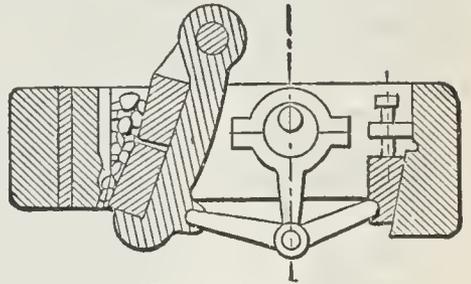

FIG. 103.

ratio varies when the angle varies, becoming infinite when the angle becomes zero.

The toggle-joint is used where great resistances are to be overcome through very small distances, as in stone-crushers (Fig. 103).

**The Inclined Plane**, as a mechanical element, is supposed perfectly hard and smooth, unless friction be considered. It assists in sustaining a heavy body by its reaction. This reaction, however, being normal to the plane, cannot entirely counteract the weight of the body, which acts vertically downward. Some other force must therefore be made to act upon the body, in order that it may be sustained.

If the sustaining force act parallel to the plane (Fig. 104), the force is to the weight as the height of the plane is to its length, measured on the incline.

If the force act parallel to the base of the plane, the power is to the weight as the height is to the base.

If the force act at any other angle, let  $i$  = the angle of the plane with the horizon, and  $e$  = the angle of the direction of the applied force with the angle of the plane.  $P : W :: \sin i : \cos e$ ;  $P \times \cos e = W \sin i$ .

Problems of the inclined plane may be solved by the parallelogram of forces thus :

Let the weight  $W$  be kept at rest on the incline by the force  $P$ , acting in the line  $bP'$ , parallel to the plane. Draw the vertical line  $ba$  to represent the weight; also  $bb'$  perpendicular to the plane, and complete the parallelogram  $b'c$ . Then the vertical weight  $ba$  is the resultant of  $bb'$ , the measure of support given by the plane to the weight, and  $bc$ , the force of gravity tending to draw the weight down the plane. The force required to maintain the weight in equilibrium is represented by this force  $bc$ . Thus the force and the weight are in the ratio of  $bc$  to  $ba$ . Since the triangle of forces  $abc$  is similar to the triangle of the incline  $ABC$ , the latter may be substituted for the former in determining the relative magnitude of the forces, and

$$P : W :: bc : ab :: BC : AB.$$

**The Wedge** is a pair of inclined planes united by their bases. In the application of pressure to the head or butt end of the wedge, to cause it to penetrate a resisting body, the applied force is to the resistance as the thickness of the wedge is to its length. Let  $t$  be the thickness,  $l$  the length,  $W$  the resistance, and  $P$  the applied force or pressure on the head of the wedge. Then, friction neglected,  $P : W :: t : l$ ;  $P = \frac{Wt}{l}$ ;  $W = \frac{Pl}{t}$ .

**The Screw** is an inclined plane wrapped around a cylinder in such a way that the height of the plane is parallel to the axis of the cylinder. If the screw is formed upon the internal surface of a hollow cylinder, it is usually called a nut. When force is applied to raise a weight or overcome a resistance by means of a screw and nut, either the screw or the nut may

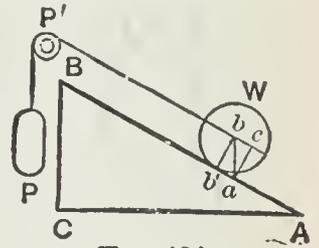

FIG. 104.

be fixed, the other being movable. The force is generally applied at the end of a wrench or lever-arm, or at the circumference of a wheel. If  $r$  = radius of the wheel or lever-arm, and  $p$  = pitch of the screw, or distance between threads, that is, the height of the inclined plane for one revolution of the screw,  $P$  = the applied force, and  $W$  = the resistance overcome, then, neglecting resistance due to friction,  $2\pi r \times P = Wp$ ;  $W = 6.283Pr \div p$ . The ratio of  $P$  to  $W$  is thus independent of the diameter of the screw. In actual screws, much of the power transmitted is lost through friction.

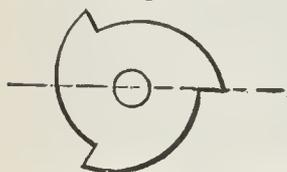

FIG. 105.

**The Cam** is a revolving inclined plane. It may be either an inclined plane wrapped around a cylinder in such a way that the height of the plane is radial to the cylinder, such as the ordinary lifting-cam, used in stamp-mills

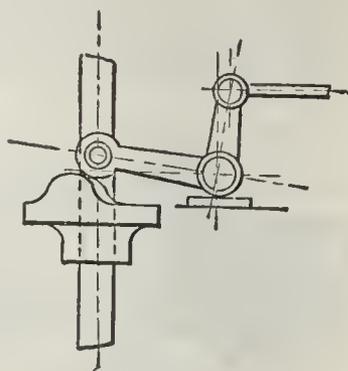

FIG. 106.

(Fig. 105), or it may be an inclined plane curved edgewise, and rotating in a plane parallel to its base (Fig. 106). The relation of the weight to the applied force is calculated in the same manner as in the case of the screw.

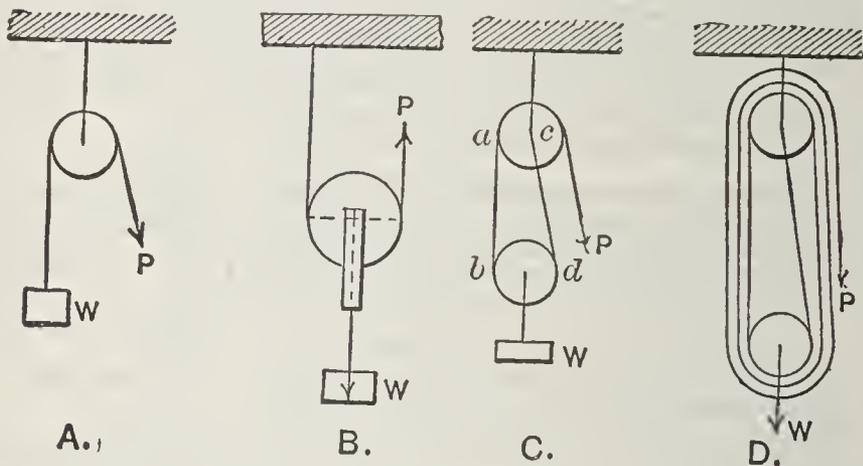

FIG. 107.

**Pulleys or Blocks.**— $P$  = force applied, or pull;  $W$  = weight lifted or resistance. In the simple pulley *A* (Fig. 107) the point  $P$  on the pulling rope descends the same amount that the weight is lifted, therefore  $P = W$ . In *B* and *C* the point  $P$  moves twice as far as the weight is lifted, therefore  $W = 2P$ . In *B* and *C* there is one movable block, and two plies of the rope engage with it. In *D* there are three sheaves in the movable block, each with two plies engaged, or six in all. Six plies of the rope are therefore shortened by the same amount that the weight is lifted, and the point  $P$  moves six times as far as the weight, consequently  $W = 6P$ . In general, the ratio of  $W$  to  $P$  is equal to the number of plies of the rope that are shortened, and also is equal to the number of plies that engage the lower block. If the lower block has 2 sheaves and the upper 3, the end of the rope is fastened to a hook in the top of the lower block, and then there are 5 plies shortened instead of 6, and  $W = 5P$ . If  $V$  = velocity of  $W$ , and  $v$  = velocity of  $P$ , then in all cases  $VW = vP$ , whatever the number of sheaves or their arrangement. If the hauling rope, at the pulling end, passes first around a sheave in the upper or stationary block, it makes no difference in what direction the rope is led from this block to the point at which the pull on the rope is applied; but if it first passes around the movable block, it is necessary that the pull be exerted in a direction parallel to the line of action of the resistance, or a line joining the centres of the two blocks, in order to obtain the maximum effect. If the rope pulls on the lower block at an angle, the block will be pulled out of the line drawn between the weight and the upper block, and the effective pull will be less than the actual pull

on the rope in the ratio of the cosine of the angle the pulling rope makes with the vertical, or line of action of the resistance, to unity.

**Differential Pulley.** (Fig. 108.)—Two pulleys, *B* and *C*, of different radii, rotate as one piece about a fixed axis, *A*. An endless chain, *BDECLKH*, passes over both pulleys. The rims of the pulleys are shaped so as to hold the chain and prevent it from slipping. One of the bights or loops in which the chain hangs, *DE*, passes under and supports the running block *F*. The other loop or bight, *HKL*, hangs freely, and is called the hauling part. It is evident that the velocity of the hauling part is equal to that of the pitch-circle of the pulley *B*.

In order that the velocity-ratio may be exactly uniform, the radius of the sheave *F* should be an exact mean between the radii of *B* and *C*.

Consider that the point *B* of the cord *BD* moves through an arc whose length = *AB*, during the same time the point *C* or the cord *CE* will move downward a distance = *AC*. The length of the bight or loop *BDEC* will be shortened by *AB - AC*, which will cause the pulley *F* to be raised half of this amount. If *P* = the pulling force on the cord *HK*, and *W* the weight lifted at *F*, then  $P \times AB = W \times \frac{1}{2}(AB - AC)$ .

To calculate the length of chain required for a differential pulley, take the following sum: Half the circumference of *A* + half the circumference of *B* + half the circumference of *F* + twice the greatest distance of *F* from *A* + the least length of loop *HKL*. The last quantity is fixed according to convenience.

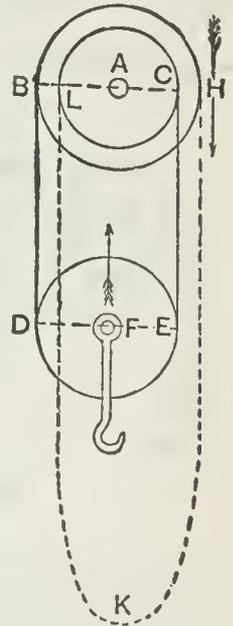

FIG. 108.

**The Differential Windlass** (Fig. 109) is identical in principle with the differential pulley, the difference in construction being that in the differential windlass the running block hangs in the bight of a rope whose two parts are wound round, and have their ends respectively made fast to two barrels of different radii, which rotate as one piece about the axis *A*. The differential windlass is little used in practice, because of the great length of rope which it requires.

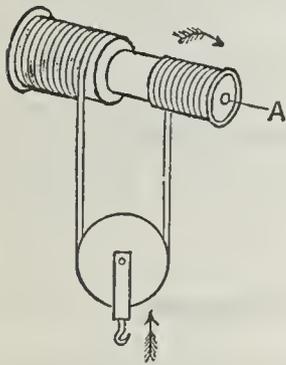

FIG. 109.

**The Differential Screw** (Fig. 110) is a compound screw of different pitches, in which the threads wind the same way. *N*<sub>1</sub> and *N*<sub>2</sub> are the two nuts; *S*<sub>1</sub>*S*<sub>1</sub>, the longer-pitched thread; *S*<sub>2</sub>*S*<sub>2</sub>, the shorter-pitched thread: in the figure both these threads are left-handed. At each turn of the screw the nut *N*<sub>2</sub> advances relatively to *N*<sub>1</sub> through a distance equal to the difference of the pitch. The use of the differential screw is to combine the slowness

of advance due to a fine pitch with the strength of thread which can be obtained by means of a coarse pitch only.

**A Wheel and Axle, or Windlass**, resembles two pulleys on one axis, having different diameters. If a weight be lifted by means of a rope wound

over the axle, the force being applied at the rim of the wheel, the action is like that of a lever of which the shorter arm is equal to the radius of the axle plus half the thickness of the rope, and the longer arm is equal to the radius of the wheel. A wheel and axle is therefore sometimes classed as a perpetual lever. If *P* = the applied force, *D* = diameter of the wheel, *W* = the weight lifted, and *d* the diameter of the axle + the diameter of the rope,  $PD = Wd$ .

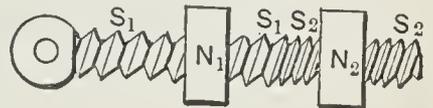

FIG. 110.

**Toothed-wheel Gearing** is a combination of two or more wheels and axles (Fig. 111). If a series of wheels and pinions gear into each other, as in the cut, friction neglected, the weight lifted, or resistance overcome, is to the force applied inversely as the distances through which they act in a given time. If *R*, *R*<sub>1</sub>, *R*<sub>2</sub> be the radii of the successive wheels, measured to the pitch-line of the teeth, and *r*, *r*<sub>1</sub>, *r*<sub>2</sub> the radii of the corresponding pinions, *P* the applied force, and *W* the weight lifted,  $P \times$

$R \times R_1 \times R_2 = W \times r \times r_1 \times r_2$ , or the applied force is to the weight as the product of the radii of the pinions is to the product of the radii of the wheels; or, as the product of the numbers expressing the teeth in each pinion is to the product of the numbers expressing the teeth in each wheel.

**Endless Screw, or Worm-gear.** (Fig. 112.)—This gear is commonly used to convert motion at high speed into motion at very slow

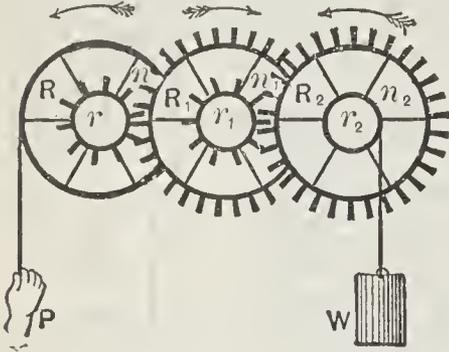

FIG. 111.

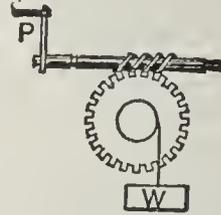

FIG. 112.

speed. When the handle  $P$  describes a complete circumference, the pitch-line of the cog-wheel moves through a distance equal to the pitch of the screw, and the weight  $W$  is lifted a distance equal to the pitch of the screw multiplied by the ratio of the diameter of the axle to the diameter of the pitch-circle of the wheel. The ratio of the applied force to the weight lifted is inversely as their velocities, friction not being considered; but the friction in the worm-gear is usually very great, amounting sometimes to three or four times the useful work done.

If  $v$  = the distance through which the force  $P$  acts in a given time, say 1 second, and  $V$  = distance the weight  $W$  is lifted in the same time,  $r$  = radius of the crank or wheel through which  $P$  acts,  $t$  = pitch of the screw, and also of the teeth on the cog-wheel,  $d$  = diameter of the axle, and  $D$  = diameter of the pitch-line of the cog-wheel,  $v = \frac{6.283 r D}{t d} \times V$ ;  $V = v \times td \div 6.283rd$ .  $Pv = WV + \text{friction}$ .

**STRESSES IN FRAMED STRUCTURES.**

Framed structures in general consist of one or more triangles, for the reason that the triangle is the one polygonal form whose shape cannot be changed without distorting one of its sides. Problems in stresses of simple framed structures may generally be solved either by the application of the triangle, parallelogram, or polygon of forces, by the principle of the lever, or by the method of moments. We shall give a few examples, referring the student to the works of Burr, Dubois, Johnson, and others for more elaborate treatment of the subject.

1. **A Simple Crane.** (Figs. 113 and 114.)— $A$  is a fixed mast,  $B$  a brace or boom,  $T$  a tie, and  $P$  the load. Required the strains in  $B$  and  $T$ . The weight  $P$ , considered as acting at the end of the boom, is held in equilibrium by three forces: first, gravity acting downwards; second, the tension in  $T$ ; and third, the thrust of  $B$ . Let the length of the line  $p$  represent the magnitude of the downward force exerted by the load, and draw a parallelogram with sides  $bt$  parallel, respectively, to  $B$  and  $T$ , such that  $p$  is the diagonal of the parallelogram. Then  $b$  and  $t$  are the components drawn to the same scale as  $p$ ,  $p$  being the resultant. Then if the length  $p$  represents the load,  $t$  is the tension in the tie, and  $b$  is the compression in the brace.

Or, more simply,  $T, B$ , and that portion of the mast included between them or  $A'$  may represent a triangle of forces, and the forces are proportional to the length of the sides of the triangle; that is, if the height of the triangle  $A'$  = the load, then  $B$  = the compression in the brace, and  $T$  = the tension in the tie; or if  $P$  = the load in pounds, the tension in  $T = P \times \frac{T}{A'}$ , and the com-

pression in  $B = P \times \frac{B}{A'}$ . Also, if  $a =$  the angle the inclined member makes with the mast, the other member being horizontal, and the triangle being right-angled, then the length of the inclined member = height of the triangle  $\times$  secant  $a$ , and the strain in the inclined member =  $P$  secant  $a$ . Also, the strain in the horizontal member =  $P \tan a$ .

The solution by the triangle or parallelogram of forces, and the equations Tension in  $T = P \times T/A'$ , and Compression in  $B = P \times B/A'$ , hold true even if the triangle is not right-angled, as in Fig. 115; but the trigonometrical rela-

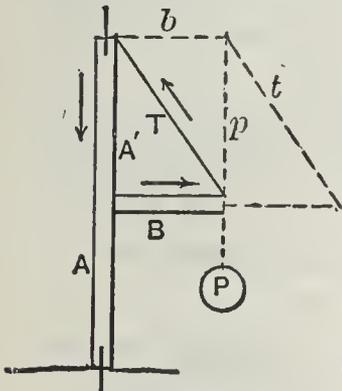

FIG. 113.

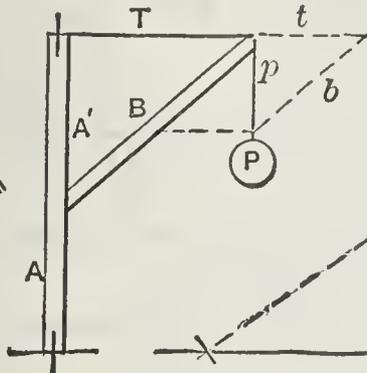

FIG. 114.

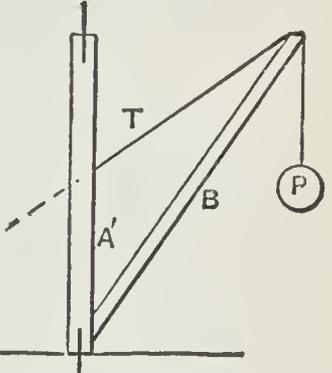

FIG. 115.

tions above given do not hold, except in the case of a right-angled triangle. It is evident that as  $A'$  decreases, the strain in both  $T$  and  $B$  increases, tending to become infinite as  $A'$  approaches zero. If the tie  $T$  is not attached to the mast, but is extended to the ground, as shown in the dotted line, the tension in it remains the same.

2. **A Guyed Crane or Derrick.** (Fig. 116.)—The strain in  $B$  is, as before,  $P \times B/A'$ ,  $A'$  being that portion of the vertical included between  $B$  and  $T$ , wherever  $T$  may be attached to  $A$ . If, however, the tie  $T$  is attached to  $B$  beneath its extremity, there may be in addition a bending strain in  $B$  due to a tendency to turn about the point of attachment of  $T$  as a fulcrum.

The strain in  $T$  may be calculated by the principle of moments. The moment of  $P$  is  $Pc$ , that is, its weight  $\times$  its perpendicular distance from the point of rotation of  $B$  on the mast. The moment of the strain on  $T$  is the product of the strain into the perpendicular distance from the line of its

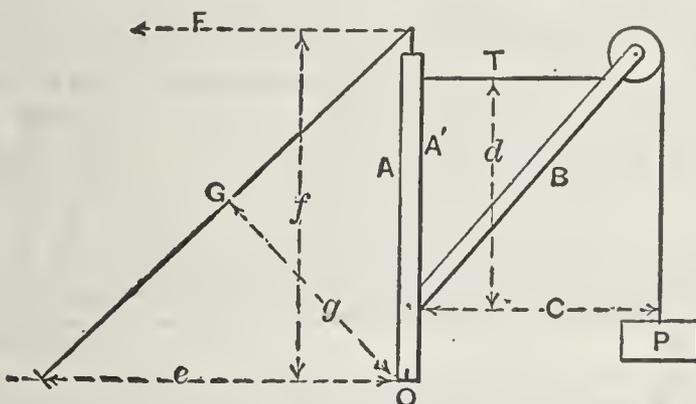

FIG. 116.

direction to the same point of rotation of  $B$ , or  $Td$ . The strain in  $T$  therefore =  $Pc \div d$ . As  $d$  decreases the strain on  $T$  increases, tending to infinity as  $d$  approaches zero.

The strain on the guy-rope is also calculated by the method of moments. The moment of the load about the bottom of the mast  $O$  is, as before,  $Pc$ . If the guy is horizontal the strain in it is  $F$  and its moment is  $Ff$ , and  $F = Pc \div f$ . If it is inclined, the moment is the strain  $G \times$  the perpendicular distance of the line of its direction from  $O$ , or  $Gg$ , and  $G = Pc \div g$ .

The guy-rope having the least strain is the horizontal one  $F$ , and the strain

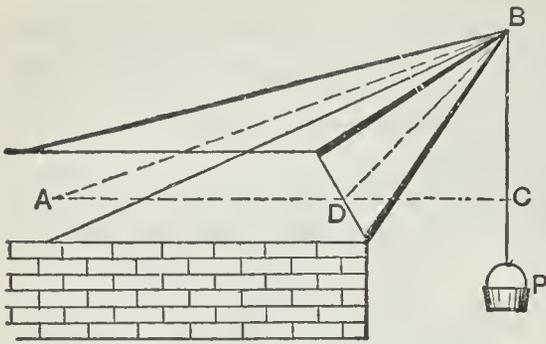

FIG. 117.

guys) make with each other to find the strain in each mast (or guy).

**Two Diagonal Braces and a Tie-rod.** (Fig. 118.)—Suppose the braces are used to sustain a single load  $P$ . Compressive stress on  $AD = \frac{1}{2}P \times AD \div AB$ ; on  $CA = \frac{1}{2}P \times CA \div AB$ . This is true only if  $CB$  and  $BD$  are of equal length, in which case  $\frac{1}{2}$  of  $P$  is supported by each abutment  $C$  and  $D$ . If they are unequal in length (Fig. 119), then, by the principle of the lever, find the reactions of the abutments  $R_1$  and  $R_2$ . If  $P$  is the load applied at the point  $B$  on the lever  $CD$ , the fulcrum being  $D$ , then  $R_1 \times CD = P \times BD$  and  $R_2 \times CD = P \times BC$ ;  $R_1 = P \times BD \div CD$ ;  $R_2 = P \times BC \div CD$ .

The strain on  $AC = R_1 \times AC \div AB$ , and on  $AD = R_2 \times AD \div AB$ .

The strain on the tie =  $R_1 \times CB \div AB = R_2 \times BD \div AB$ .

in  $G =$  the strain in  $F \times$  the secant of the angle between  $F$  and  $G$ . As  $G$  is made more nearly vertical  $g$  decreases, and the strain increases, becoming infinite when  $g = 0$ .

**3. Shear-poles with Guys.** (Fig. 117.)—First assume that the two masts act as one placed at  $BD$ , and the two guys as one at  $AB$ . Calculate the strain in  $BD$  and  $AB$  as in Fig. 115. Multiply half the strain in  $BD$  (or  $AB$ ) by the secant of half the angle the two masts (or

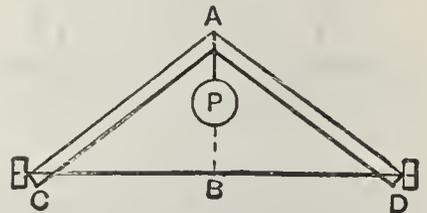

FIG. 118.

When  $CB = BD$ ,  $R_1 = R_2$ . The strain on  $CB$  and  $BD$  is the same, whether the braces are of equal length or not, and is equal to  $\frac{1}{2}P \times \frac{1}{2}CD \div AB$ .

If the braces support a uniform load, as a pair of rafters, the strains caused by such a load are equivalent to that caused by one half of the load applied at the centre. The horizontal thrust of the braces against each other at the

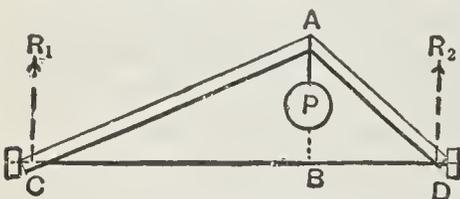

FIG. 119.

apex equals the tensile strain in the tie.

**King-post Truss or Bridge.** (Fig. 120.)—If the load is distributed over the whole length of the truss, the effect is the same as if half the load were placed at the centre, the other half being carried by the abutments. Let  $P =$  one half the load on the truss, then tension in the vertical tie  $AB = P$ . Compression in each of the inclined braces =  $\frac{1}{2}P \times AD \div AB$ . Tension in the tie  $CD = \frac{1}{2}P \times BD \div AB$ . Horizontal thrust of inclined brace  $AD$  at  $D =$  the tension in the tie. If  $W =$  the total load on one truss uniformly distributed,  $l =$  its length and  $d =$  its depth, then the tension on the horizontal tie =  $\frac{Wl}{8d}$ .

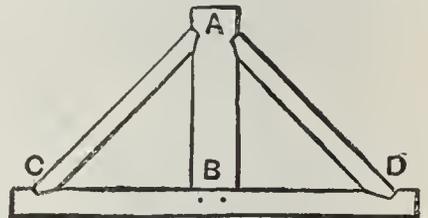

FIG. 120.

**Inverted King-post Truss.** (Fig. 121.)—If  $P =$  a load applied at  $B$ , or one half of a uniformly distributed load, then compression on  $AB = P$  (the floor-beam  $CD$  not being considered to have any resistance to a slight bending). Tension on  $AC$  or  $AD = \frac{1}{2}P \times AD \div AB$ . Compression on  $CD = \frac{1}{2}P \times BD \div AB$ .

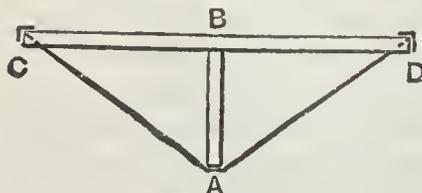

FIG. 121.

**Queen-post Truss.** (Fig. 122.)—If uniformly loaded, and the queen-posts divide the length into three equal bays, the load may be considered to be divided into three equal parts, two parts of which,  $P_1$  and  $P_2$ , are concentrated at the panel joints

and the remainder is equally divided between the abutments and supported by them directly. The two parts  $P_1$  and  $P_2$  only are considered to affect

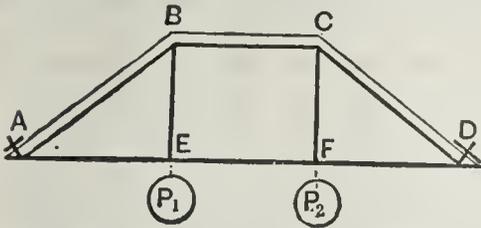

FIG. 122.

the members of the truss. Strain in the vertical ties  $BE$  and  $CF$  each equals  $P_1$  or  $P_2$ . Strain on  $AB$  and  $CD$  each =  $P_1 \times CD \div CF$ . Strain on the tie  $AE$  or  $EF$  or  $ED = P_1 \times FD \div CF$ . Thrust on  $BC =$  tension on  $EF$ .

For stability to resist heavy unequal loads the queen-post truss should have diagonal braces from  $B$  to  $F$  and from  $C$  to  $E$ .

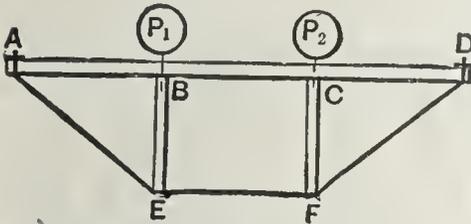

FIG. 123.

**Inverted Queen-post Truss.** (Fig. 123.)—Compression on  $EB$  and  $FC$  each =  $P_1$  or  $P_2$ . Compression on  $AB$  or  $BC$  or  $CD = P_1 \times AB \div EB$ . Tension on  $AE$  or  $FD = P_1 \times AE \div EB$ . Tension on  $EF =$  compression on  $BC$ . For stability to resist unequal loads, ties should be run from  $C$  to  $E$  and from  $B$  to  $F$ .

**Burr Truss of Five Panels.** (Fig. 124.)—Four fifths of the load may be taken as concentrated at the points  $E, K, L$  and  $F$ , the other fifth being

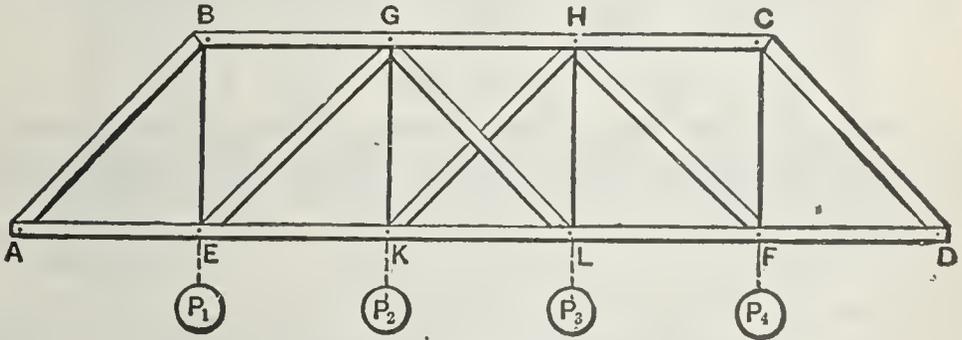

FIG. 124.

supported directly by the two abutments. For the strains in  $BA$  and  $CD$  the truss may be considered as a queen-post truss, with the loads  $P_1, P_2$  concentrated at  $E$  and the loads  $P_3, P_4$  concentrated at  $F$ . Then, compressive strain on  $AB = (P_1 + P_2) \times AB \div BE$ . The strain on  $CD$  is the same if the loads and panel lengths are equal. The tensile strain on  $BE$  or  $CF = P_1 + P_2$ . That portion of the truss between  $E$  and  $F$  may be considered as a smaller queen-post truss, supporting the loads  $P_2, P_3$  at  $K$  and  $L$ . The strain on  $EG$  or  $HF = P_2 \times EG \div GK$ . The diagonals  $GL$  and  $KH$  receive no strain unless the truss is unequally loaded. The verticals  $GK$  and  $HL$  each receive a tensile strain equal to  $P_2$  or  $P_3$ .

For the strain in the horizontal members:  $BG$  and  $CH$  receive a thrust equal to the horizontal component of the thrust in  $AB$  or  $CD$ ,  $= (P_1 + P_2) \times \tan \text{angle } ABE$ , or  $(P_1 + P_2) \times AE \div BE$ .  $GH$  receives this thrust and also, in addition, a thrust equal to the horizontal component of the thrust in  $EG$  or  $HF$ , or, in all,  $(P_1 + P_2 + P_3) \times AE \div BE$ .

The tension in  $AE$  or  $FD$  equals the thrust in  $BG$  or  $HC$ , and the tension in  $EK, KL$ , and  $LF$  equals the thrust in  $GH$ .

**Pratt or Whipple Truss.** (Fig. 125.)—In this truss the diagonals are ties, and the verticals are struts or columns.

*Calculation by the method of distribution of strains:* Consider first the load  $P_1$ . The truss having six bays or panels,  $5/6$  of the load is transmitted to the abutment  $H$ , and  $1/6$  to the abutment  $O$ , on the principle of the lever. As the five sixths must be transmitted through  $JA$  and  $AH$ , write on these members the figure 5. The one sixth is transmitted successively through  $JC, CK, KD, DL$ , etc., passing alternately through a tie and a strut. Write on these members, up to the strut  $GO$  inclusive, the figure 1. Then consider the load  $P_2$ , of which  $4/6$  goes to  $AH$  and  $2/6$  to  $GO$ . Write on  $KB, BJ, JA$ , and  $AH$  the figure 4, and on  $KD, DL, LE$ , etc., the figure 2. The load  $P_2$

transmit  $3/6$  in each direction; write 3 on each of the members through which this stress passes, and so on for all the loads, when the figures on the several members will appear as on the cut. Adding them up, we have the following totals :

Tension on diagonals	}	<i>AJ</i>	<i>BH</i>	<i>BK</i>	<i>CJ</i>	<i>CL</i>	<i>DK</i>	<i>DM</i>	<i>EL</i>	<i>EN</i>	<i>FM</i>	<i>FO</i>	<i>GN</i>
		15	0	10	1	6	3	3	6	1	10	0	15
Compression on verticals	}	<i>AH</i>	<i>BJ</i>	<i>CK</i>	<i>DL</i>	<i>EM</i>	<i>FN</i>	<i>GO</i>					
		15	10	7	6	7	10	15					

Each of the figures in the first line is to be multiplied by  $1/6P \times \secant$  of angle *H AJ*, or  $1/6P \times AJ \div AH$ , to obtain the tension, and each figure in the lower line is to be multiplied by  $1/6P$  to obtain the compression. The diagonals *HB* and *FO* receive no strain.

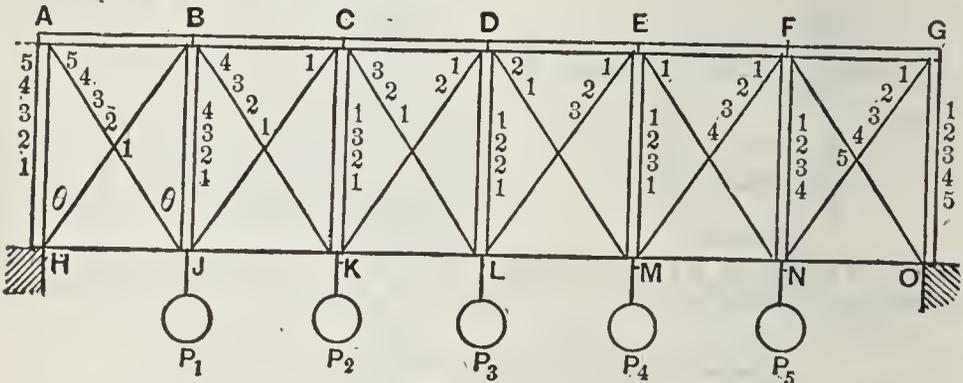

FIG. 125.

It is common to build this truss with a diagonal strut at *HB* instead of the post *HA* and the diagonal *AJ*; in which case  $5/6$  of the load *P* is carried through *JB* and the strut *BH*, which latter then receives a strain =  $15/6P \times \secant$  of *HBJ*.

The strains in the upper and lower horizontal members or chords increase from the ends to the centre, as shown in the case of the Burr truss. *AB* receives a thrust equal to the horizontal component of the tension in *AJ*, or  $15/6P \times \tan$  *AJB*. *BC* receives the same thrust + the horizontal component of the tension in *BK*, and so on. The tension in the lower chord of each panel is the same as the thrust in the upper chord of the same panel. (For calculation of the chord strains by the method of moments, see below.)

The maximum thrust or tension is at the centre of the chords and is equal to  $\frac{WL}{8D}$ , in which *W* is the total load supported by the truss, *L* is the length, and *D* the depth. This is the formula for maximum stress in the chords of a truss of any form whatever.

The above calculation is based on the assumption that all the loads *P*<sub>1</sub>, *P*<sub>2</sub>, etc., are equal. If they are unequal the value of each has to be taken into account in distributing the strains. Thus the tension in *AJ*, with unequal loads, instead of being  $15 \times 1/6 P \secant \theta$  would be  $\sec \theta \times (5/6 P_1 + 4/6 P_2 + 3/6 P_3 + 2/6 P_4 + 1/6 P_5)$ . Each panel load, *P*<sub>1</sub> etc., includes its fraction of the weight of the truss.

**General Formula for Strains in Diagonals and Verticals.**

—Let *n* = total number of panels, *x* = number of any vertical considered from the nearest end, counting the end as 1, *r* = rolling load for each panel, *P* = total load for each panel,

$$\text{Strain on verticals} = \frac{[(n-x) + (n-x)^2 - (x-1) + (x-1)^2]P}{2n} + \frac{r(x-1) + (x-1)^2}{2n}$$

For a uniformly distributed load, leave out the last term,  
 $[r(x-1) + (x-1)^2] \div 2n$ .

Strain on principal diagonals = strain on verticals  $\times \secant \theta$ , that is  $\secant$  of the angle the diagonal makes with the vertical.

Strain on the counterbraces : The strain on the counterbrace in the first panel is 0, if the load is uniform. On the 2d, 3d, 4th, etc., it is  $P \secant \theta \times \frac{1}{n}, \frac{1+2}{n}, \frac{1+2+3}{n}$ , etc., *P* being the total load in one panel.

**Strain in the Chords—Method of Moments.**—Let the truss be uniformly loaded, the total load acting on it =  $W$ . Weight supported at each end, or reaction of the abutment =  $W/2$ . Length of the truss =  $L$ . Weight on a unit of length =  $W/L$ . Horizontal distance from the nearest abutment to the point (say  $M$  in Fig. 125) in the chord where the strain is to be determined =  $x$ . Horizontal strain at that point (tension on the lower chord, compression in the upper) =  $H$ . Depth of the truss =  $D$ . By the method of moments we take the difference of the moments, about the point  $M$ , of the reaction of the abutment and of the load between  $M$  and the abutments, and equate that difference with the moment of the resistance, or of the strain in the horizontal chord, considered with reference to a point in the opposite chord, about which the truss would turn if the first chord were severed at  $M$ .

The moment of the reaction of the abutment is  $Wx/2$ . The moment of the load from the abutment to  $M$  is  $W/Lx \times$  the distance of its centre of gravity from  $M$ , which is  $x/2$ , or moment =  $Wx^2/2L$ . Moment of the stress in the chord =  $HD = \frac{Wx}{2} - \frac{Wx^2}{2L}$ , whence  $H = \frac{W}{2D} \left( x - \frac{x^2}{L} \right)$ . If  $x = 0$  or  $L$ ,  $H = 0$ . If  $x = L/2$ ,  $H = \frac{WL}{8D}$ , which is the horizontal strain at the middle of the chords, as before given.

**The Howe Truss.** (Fig. 126.)—In the Howe truss the diagonals are struts, and the verticals are ties. The calculation of strains may be made

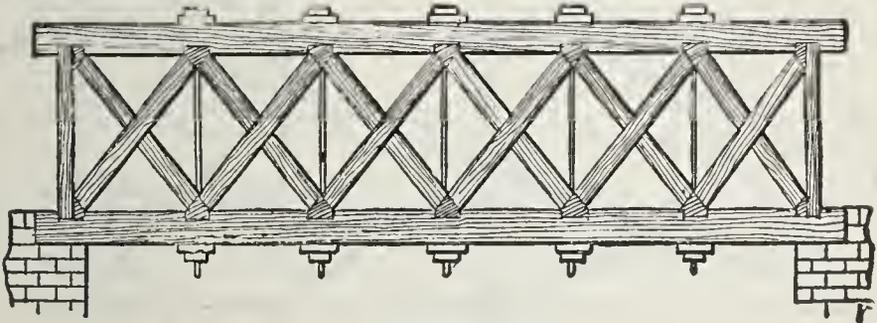

FIG. 126.

in the same method as described above for the Pratt truss.

**The Warren Girder.** (Fig. 127.)—In the Warren girder, or triangular truss, there are no vertical struts, and the diagonals may transmit either

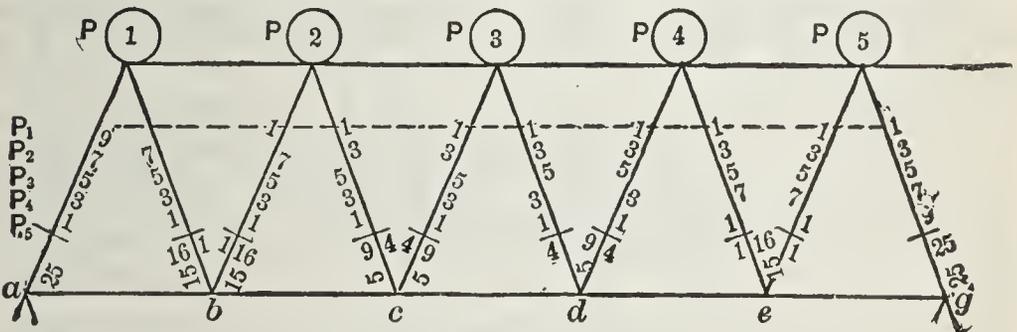

FIG. 127.

tension or compression. The strains in the diagonals may be calculated by the method of distribution of strains as in the case of the rectangular truss.

On the principle of the lever, the load  $P_1$  being  $1/10$  of the length of the span from the line of the nearest support  $a$ , transmits  $9/10$  of its weight to  $a$  and  $1/10$  to  $g$ . Write 9 on the right hand of the strut  $1a$ , to represent the compression, and 1 on the right hand of  $1b$ ,  $2c$ ,  $3d$ , etc., to represent compression, and on the left hand of  $b^2$ ,  $c^3$ , etc., to represent tension. The load  $P_2$  transmits  $7/10$  of its weight to  $a$  and  $3/10$  to  $g$ . Write 7 on each member from 2 to  $a$  and 3 on each member from 2 to  $g$ , placing the figures representing compression on the right hand of the member, and those representing tension on the left. Proceed in the same manner with all the loads, then

sum up the figures on each side of each diagonal, and write the difference of each sum beneath, and on the side of the greater sum, to show whether the difference represents tension or compression. The results are as follows: Compression,  $1a$ , 25;  $2b$ , 15;  $3c$ , 5;  $3d$ , 5;  $4e$ , 15;  $5g$ , 25. Tension,  $1b$ , 15;  $2c$ , 5;  $4d$ , 5;  $5e$ , 15. Each of these figures is to be multiplied by  $1/10$  of one of the loads as  $P_1$ , and by the secant of the angle the diagonals make with a vertical line.

The strains in the horizontal chords may be determined by the method of moments as in the case of rectangular trusses.

**Roof-truss.**—*Solution by Method of Moments.*—The calculation of strains in structures by the method of statical moments consists in taking a cross-section of the structure at a point where there are not more than three members (struts, braces, or chords).

To find the strain in either one of these members take the moment about the intersection of the other two as an axis of rotation. The sum of the moments of these members must be 0 if the structure is in equilibrium. But the moments of the two members that pass through the point of reference or axis are both 0, hence one equation containing one unknown quantity can be found for each cross-section.

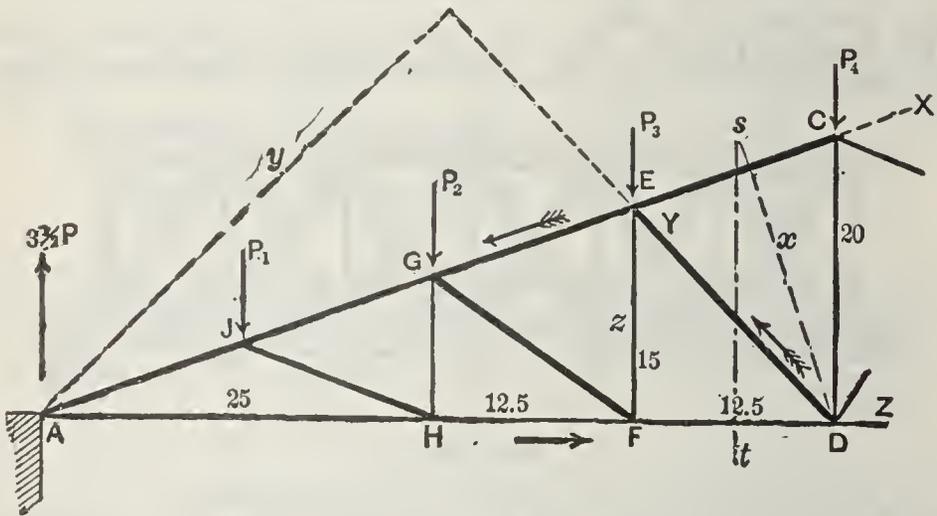

FIG. 128.

In the truss shown in Fig. 128 take a cross-section at  $ts$ , and determine the strain in the three members cut by it, viz.,  $CE$ ,  $ED$ , and  $DF$ . Let  $X$  = force exerted in direction  $CE$ ,  $Y$  = force exerted in direction  $DE$ ,  $Z$  = force exerted in direction  $FD$ .

For  $X$  take its moment about the intersection of  $Y$  and  $Z$  at  $D = Xx$ . For  $Y$  take its moment about the intersection of  $X$  and  $Z$  at  $A = Yy$ . For  $Z$  take its moment about the intersection of  $X$  and  $Y$  at  $E = Zz$ . Let  $z = 15$ ,  $x = 18.6$ ,  $y = 38.4$ ,  $AD = 50$ ,  $CD = 20$  ft. Let  $P_1, P_2, P_3, P_4$  be equal loads, as shown, and  $3\frac{1}{2}P$  the reaction of the abutment  $A$ .

The sum of all the moments taken about  $D$  or  $A$  or  $E$  will be 0 when the structure is at rest. Then  $-Xx + 3.5P \times 50 - P_3 \times 12.5 - P_2 \times 25 - P_1 \times 37.5 = 0$ .

The  $+$  signs are for moments in the direction of the hands of a watch or "clockwise" and  $-$  signs for the reverse direction or anti-clockwise. Since  $P = P_1 = P_2 = P_3$ ,  $-18.6X + 175P - 75P = 0$ ;  $-18.6X = -100P$ ;  $X = 100P \div 18.6 = 5.376P$ .

$-Yy + P_3 \times 37.5 + P_2 \times 25 + P_1 \times 12.5 = 0$ ;  $38.4Y = 75P$ ;  $Y = 75P \div 38.4 = 1.953P$ .

$-Zz + 3.5P \times 37.5 - P_1 \times 25 - P_2 \times 12.5 - P_3 \times 0 = 0$ ;  $15Z = 93.75P$ ;  $Z = 6.25P$ .

In the same manner the forces exerted in the other members have been found as follows:  $EG = 6.73P$ ;  $GJ = 8.07P$ ;  $JA = 9.42P$ ;  $JH = 1.35P$ ;  $GF = 1.59P$ ;  $AH = 8.75P$ ;  $HF = 7.50P$ .

**The Fink Roof-truss.** (Fig. 129).—An analysis by Prof. P. H. Philbrick (*Van N. Mag.*, Aug. 1880) gives the following results:

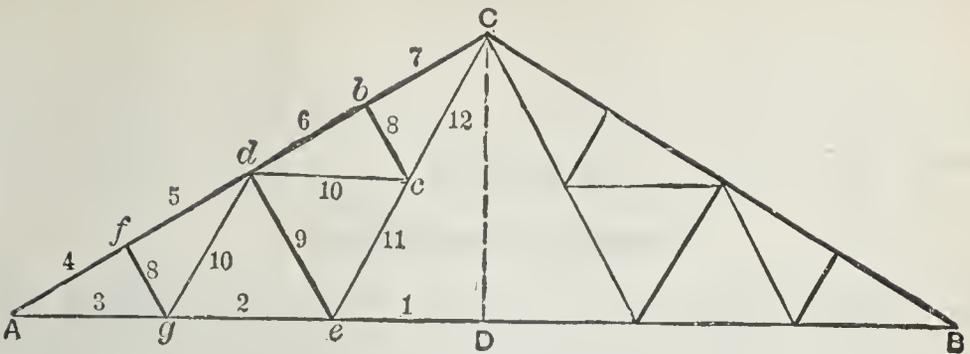

FIG. 129.

$W$  = total load on roof;  
 $N$  = No. of panels on both rafters;  
 $W/N = P$  = load at each joint  $b, d, f$ , etc.;  
 $V$  = reaction at  $A = \frac{1}{2}W = \frac{1}{2}NP = 4P$ ;  
 $AD = S$ ;  $AC = L$ ;  $CD = D$ ;  
 $t_1, t_2, t_3$  = tension on  $De, eg, gA$ , respectively;  
 $c_1, c_2, c_3, c_4$  = compression on  $Cb, bd, df$ , and  $fA$ .

Strains in

1, or $De = t_1 = 2PS \div D$ ;	7, or $bC = c_1 = 7/2 PL/D - 3 PD/L$ ;
2, " $eg = t_2 = 3PS \div D$ ;	8, " $bc$ or $fg = PS \div L$ ;
3, " $gA = t_3 = 7/2 PS \div D$ ;	9, " $de = 2PS \div L$ ;
4, " $Af = c_4 = 7/2 PL \div D$ ;	10, " $cd$ or $dg = \frac{1}{2} PS \div D$ ;
5, " $fd = c_3 = 7/2 PL/D - PD/L$ ;	11, " $ec = PS \div D$ ;
6, " $db = c_2 = 7/2 PL/D - 2PD/L$ ;	12, " $cC = 3/2 PS \div D$ .

*Example.*—Given a Fink roof-truss of span 64 ft., depth 16 ft., with four panels on each side, as in the cut; total load 32 tons, or 4 tons each at the points  $f, d, b, C$ , etc. (and 2 tons each at  $A$  and  $B$ , which transmit no strain to the truss members). Here  $W = 32$  tons,  $P = 4$  tons,  $S = 32$  ft.,  $D = 16$  ft.,  $L = \sqrt{S^2 + D^2} = 2.236 \times D$ .  $L + D = 2.236$ ,  $D \div L = .4472$ ,  $S \div D = 2$ ,  $S + L = .8944$ . The strains on the numbered members then are as follows:

1, $2 \times 4 \times 2 = 16$ tons;	7, $31.3 - 12 \times .447 = 25.94$ tons.
2, $3 \times 4 \times 2 = 24$ "	8, $4 \times .8944 = 3.58$ "
3, $7/2 \times 4 \times 2 = 28$ "	9, $8 \times .8944 = 7.16$ "
4, $7/2 \times 4 \times 2.236 = 31.3$ "	10, $2 \times 2 = 4$ "
5, $31.3 - 4 \times .447 = 29.52$ "	11, $4 \times 2 = 8$ "
6, $31.3 - 8 \times .447 = 27.72$ "	12, $6 \times 2 = 12$ "

**The Economical Angle.**—A structure of triangular form, Fig. 129a, is supported at  $a$  and  $b$ . It sustains any load  $L$ , the elements  $cc$  being in compression and  $t$  in tension. Required the angle  $\theta$  so that the total weight of the structure shall be a minimum. F. R. Honey (*Sci. Am. Supp.*, Jan. 17, 1895) gives a solution of this problem, with the result  $\tan \theta = \sqrt{\frac{C+T}{T}}$ ,

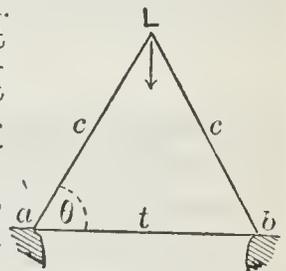

FIG. 129a.

in which  $C$  and  $T$  represent the crushing and the tensile strength respectively of the material employed. It is applicable to any material. For  $C = T$ ,  $\theta = 54\frac{3}{4}^\circ$ . For  $C = 0.4T$  (yellow pine),  $\theta = 49\frac{3}{4}^\circ$ . For  $C = 0.8T$  (soft steel),  $\theta = 53\frac{1}{4}^\circ$ . For  $C = 6T$  (cast iron),  $\theta = 69\frac{1}{4}^\circ$ .

## HEAT.

## THERMOMETERS.

The Fahrenheit thermometer is generally used in English-speaking countries, and the Centigrade, or Celsius thermometer, in countries that use the metric system. In many scientific treatises in English, however, the Centigrade temperatures are also used, either with or without their Fahrenheit equivalents. The Réaumur thermometer is used to some extent on the Continent of Europe.

In the Fahrenheit thermometer the freezing-point of water is taken at  $32^{\circ}$ , and the boiling-point of water at mean atmospheric pressure at the sea-level, 14.7 lbs. per sq. in., is taken at  $212^{\circ}$ , the distance between these two points being divided into 180°. In the Centigrade and Réaumur thermometers the freezing-point is taken at  $0^{\circ}$ . The boiling-point is  $100^{\circ}$  in the Centigrade scale, and  $80^{\circ}$  in the Réaumur.

1 Fahrenheit degree =  $\frac{5}{9}$  deg. Centigrade =  $\frac{4}{9}$  deg. Réaumur.

1 Centigrade degree =  $\frac{9}{5}$  deg. Fahrenheit =  $\frac{4}{5}$  deg. Réaumur.

1 Réaumur degree =  $\frac{9}{4}$  deg. Fahrenheit =  $\frac{5}{4}$  deg. Centigrade.

Temperature Fahrenheit =  $\frac{9}{5} \times \text{temp. C.} + 32^{\circ} = \frac{9}{4} \text{ R.} + 32^{\circ}$ .

Temperature Centigrade =  $\frac{5}{9} (\text{temp. F.} - 32^{\circ}) = \frac{5}{4} \text{ R.}$

Temperature Réaumur =  $\frac{4}{5} \text{ temp. C.} = \frac{4}{9} (\text{F.} - 32^{\circ})$ .

**Mercurial Thermometer.** (Rankine, S. E., p. 234.)—The rate of expansion of mercury with rise of temperature increases as the temperature becomes higher; from which it follows, that if a thermometer showing the dilatation of mercury simply were made to agree with an air thermometer at  $32^{\circ}$  and  $212^{\circ}$ , the mercurial thermometer would show lower temperatures than the air thermometer between those standard points, and higher temperatures beyond them.

For example, according to Regnault, when the air thermometer marked  $350^{\circ} \text{ C.}$  ( $= 662^{\circ} \text{ F.}$ ), the mercurial thermometer would mark  $362.16^{\circ} \text{ C.}$  ( $= 683.89^{\circ} \text{ F.}$ ), the error of the latter being in excess  $12.16^{\circ} \text{ C.}$  ( $= 21.89^{\circ} \text{ F.}$ ).

Actual mercurial thermometers indicate intervals of temperature proportional to the difference between the expansion of mercury and that of glass.

The inequalities in the rate of expansion of the glass (which are very different for different kinds of glass) correct, to a greater or less extent, the errors arising from the inequalities in the rate of expansion of the mercury.

For practical purposes connected with heat engines, the mercurial thermometer made of common glass may be considered as sensibly coinciding with the air-thermometer at all temperatures not exceeding  $500^{\circ} \text{ F.}$

## PYROMETRY.

**Principles Used in Various Pyrometers.**—Contraction of clay by heat, as in the Wedgwood pyrometer used by potters. Not accurate, as the contraction varies with the quality of the clay.

Expansion of air, as in the air-thermometers, Wiborgh's pyrometer, Uehling and Steinbart's pyrometer, etc.

Specific heat of solids, as in the copper-ball, platinum-ball, and fire-clay pyrometers.

Relative expansion of two metals or other substances, as copper and iron, as in Brown's and Bulkley's pyrometers, etc.

Melting-points of metals, or other substances, as in approximate determinations of temperature by melting pieces of zinc, lead, etc.

Measurement of strength of a thermo-electric current produced by heating the junction of two metals, as in Le Chatelier's pyrometer.

Changes in electric resistance of platinum, as in the Siemens pyrometer.

Mixture of hot and cold air, as in Hobson's hot-blast pyrometer.

Time required to heat a weighed quantity of water enclosed in a vessel, as in the water pyrometer.

**Thermometer for Temperatures up to  $950^{\circ} \text{ F.}$** —Mercury with compressed nitrogen in the tube above the mercury. Made by Queen & Co., Philadelphia.

**TEMPERATURES, CENTIGRADE AND  
FAHRENHEIT.**

**Platinum or Copper Ball Pyrometer.**—A weighed piece of platinum, copper, or iron is allowed to remain in the furnace or heated chamber till it has attained the temperature of its surroundings. It is then suddenly taken out and dropped into a vessel containing water of a known weight and temperature. The water is stirred rapidly and its maximum temperature taken. Let  $W$  = weight of the water,  $w$  the weight of the ball,  $t$  = the original and  $T$  the final heat of the water, and  $S$  the specific heat of the metal; then the temperature of fire may be found from the formula

$$x = \frac{W(T - t)}{wS} + T.$$

The mean specific heat of platinum between 32° and 446° F. is .03333 or 1/30 that of water, and it increases with the temperature about .000305 for each 100° F. For a fuller description, by J. C. Hoadley, see *Trans. A. S. M. E.*, vi. 702. Compare also Henry M. Howe, *Trans. A. I. M. E.*, xviii. 728.

For accuracy corrections are required for variations in the specific heat of the water and of the metal at different temperatures, for loss of heat by radiation from the metal during the transfer from the furnace to the water, and from the apparatus during the heating of the water; also for the heat-absorbing capacity of the vessel containing the water.

Fire-clay or fire-brick may be used instead of the metal ball.

**Le Chatelier's Thermo-electric Pyrometer.**—For a very full description see paper by Joseph Struthers, *School of Mines Quarterly*, vol. xii, 1891; also, paper read by Prof. Roberts-Austen before the Iron and Steel Institute, May 7, 1891.

The principle upon which this pyrometer is constructed is the measurement of a current of electricity produced by heating a couple composed of two wires, one platinum and the other platinum with 10% rhodium—the current produced being measured by a galvanometer.

The composition of the gas which surrounds the couple has no influence on the indications.

When temperatures above 2500° F. are to be studied, the wires must have an isolating support and must be of good length, so that all parts of a furnace can be reached.

For a Siemens furnace, about 11½ feet is the general length. The wires are supported in an iron tube, ½ inch interior diameter and held in place by a cylinder of refractory clay having two holes bored through, in which the wires are placed. The shortness of time (five seconds) allows the temperature to be taken without deteriorating the tube.

Tests made by this pyrometer in measuring furnace temperatures under a great variety of conditions show that the readings of the scale uncorrected are always within 45° F. of the correct temperature, and in the majority of industrial measurements this is sufficiently accurate. Le Chatelier's pyrometer is sold by Queen & Co., of Philadelphia.

**Graduation of Le Chatelier's Pyrometer.**—W. C. Roberts-Austen in his *Researches on the Properties of Alloys*, *Proc. Inst. M. E.* 1892, says: 'The electromotive force produced by heating the thermo-junction to any given temperature is measured by the movement of the spot of light on the scale graduated in millimetres. A formula for converting the divisions of the scale into thermometric degrees is given by M. Le Chatelier; but it is better to calibrate the scale by heating the thermo-junction to temperatures which have been very carefully determined by the aid of the air-thermometer, and then to plot the curve from the data so obtained. Many fusion and boiling-points have been established by concurrent evidence of various kinds, and are now very generally accepted. The following table contains certain of these :

Deg. F.	Deg. C.		Deg. F.	Deg. C.	
212	100	Water boils.	1733	945	Silver melts.
618	326	Lead melts.	1859	1015	Potassium sul-
676	358	Mercury boils.			phate melts.
779	415	Zinc melts.	1913	1045	Gold melts.
838	448	Sulphur boils.	1929	1054	Copper melts.
1157	625	Aluminium melts.	2732	1500	Palladium melts.
1229	665	Selenium boils.	3227	1775	Platinum melts.

**The Temperatures Developed in Industrial Furnaces.**—M. Le Chatelier states that by means of his pyrometer he has discovered that the temperatures which occur in melting steel and in other industrial operations have been hitherto overestimated.

M. Le Chatelier finds the melting heat of white cast iron 1135° (2075° F.), and that of gray cast iron 1220° (2228° F.). Mild steel melts at 1475° (2687° F.), semi-mild at 1455° (2651° F.), and hard steel at 1410° (2570° F.). The furnace for hard porcelain at the end of the baking has a heat of 1370° (2498° F.). The heat of a normal incandescent lamp is 1800° (3272° F.), but it may be pushed to beyond 2100° (3812° F.).

Prof. Roberts-Austen (Recent Advances in Pyrometry, Trans. A. I. M. E., Chicago Meeting, 1893) gives an excellent description of modern forms of pyrometers. The following are some of his temperature determinations.

#### GOLD-MELTING, ROYAL MINT.

	Degrees. Centigrade.	Degrees. Fahr.
Temperature of standard alloy, pouring into moulds. . . . .	1180	2156
Temperature of standard alloy, pouring into moulds (on a previous occasion, by thermo-couple).....	1147	2097
Annealing blanks for coinage, temperature of chamber..	890	1634

#### SILVER-MELTING, ROYAL MINT.

Temperature of standard alloy, pouring into mould.....	980	1796
--	-----	------

#### TEN-TON OPEN-HEARTH FURNACE, WOOLWICH ARSENAL.

Temperature of steel, 0.3% carbon, pouring into ladle.....	1645	2993
Steel, 0.3% carbon, pouring into large mould.....	1580	2876
Reheating furnace, interior.....	920	1706
Cupola furnace, No. 2 cast iron, pouring into ladle.....	1600	2912

The following determinations have been effected by M. Le Chatelier:

#### BESSEMER PROCESS.

##### Six-ton Converter.

	Degrees. Centigrade	Degrees Fahr.
A. Bath of slag.....	1580	2876
B. Metal in ladle.....	1640	2984
C. Metal in ingot mould.....	1580	2876
D. Ingot in reheating furnace.....	1200	2192
E. Ingot under the hammer.....	1080	1976

#### OPEN-HEARTH FURNACE (Siemens).

##### Semi-Mild Steel.

A. Fuel gas near gas generator.....	720	1328
B. Fuel gas entering into bottom of regenerator chamber	400	752
C. Fuel gas issuing from regenerator chamber.....	1200	2192
Air issuing from regenerator chamber.....	1000	1832
Chimney gases. Furnace in perfect condition.....	300	590
End of the melting of pig charge.....	1420	2588
Completion of conversion.....	1500	2732
Molten steel. In the ladle—Commencement of casting..	1580	2876
End of casting.....	1490	2714
In the moulds.....	1520	2768

For very mild (soft) steel the temperatures are higher by 50° C.

#### SIEMENS CRUCIBLE OR POT FURNACE.

1600° C., 2912° F.

#### ROTARY PUDDLING FURNACE.

	Degrees C.	Degrees F
Furnace.....	1340-1230	2444-2246
Puddled ball—End of operation.....	1330	2426

#### BLAST-FURNACE (Gray-Bessemer Pig).

Opening in face of tuyere.....	1930	3506
Molten metal—Commencement of fusion.....	1400	2552
End, or prior to tapping.....	1570	2858

#### HOFFMAN RED-BRICK KILN.

Burning temperatures.....	1100	2012
---------------------------	------	------

**Hobson's Hot-blast Pyrometer** consists of a brass chamber having three hollow arms and a handle. The hot blast enters one of the arms and induces a current of atmospheric air to flow into the second arm. The two currents mix in the chamber and flow out through the third arm, in which the temperature of the mixture is taken by a mercury thermometer. The openings in the arms are adjusted so that the proportion of hot blast to the atmospheric air remains the same.

**The Wiborgh Air-pyrometer.** (E. Trotz, Trans. A. I. M. E. 1892.)—The inventor using the expansion-coefficient of air, as determined by Gay-Lussac, Dulon, Rudberg, and Regnault, bases his construction on the following theory: If an air-volume,  $V$ , enclosed in a porcelain globe and connected through a capillary pipe with the outside air, be heated to the temperature  $T$  (which is to be determined) and thereupon the connection be discontinued, and there be then forced into the globe containing  $V$  another volume of air  $V'$  of known temperature  $t$ , which was previously under atmospheric pressure  $H$ , the additional pressure  $h$ , due to the addition of the air-volume  $V'$  to the air-volume  $V$ , can be measured by a manometer. But this pressure is of course a function of the temperature  $T$ . Before the introduction of  $V'$ , we have the two separate air-volumes,  $V$  at the temperature  $T$  and  $V'$  at the temperature  $t$ , both under the atmospheric pressure  $H$ . After the forcing in of  $V'$  into the globe, we have, on the contrary, only the volume  $V$  of the temperature  $T$ , but under the pressure  $H + h$ .

The Wiborgh Air-pyrometer is adapted for use at blast-furnaces, smelting-works, hardening and tempering furnaces, etc., where determinations of temperature from  $0^\circ$  to  $2400^\circ$  F. are required.

**Sege's Fire-clay Pyrometer.** (H. M. Howe, *Eng. and Mining Jour.*, June 7, 1890.)—Professor Seger uses a series of slender triangular fire-clay pyramids, about 3 inches high and  $\frac{5}{8}$  inch wide at the base, and each a little less fusible than the next: these he calls "normal pyramids" ("normal-kegel"). When the series is placed in a furnace whose temperature is gradually raised, one after another will bend over as its range of plasticity is reached; and the temperature at which it has bent, or "wept," so far that its apex touches the hearth of the furnace or other level surface on which it is standing, is selected as a point on Seger's scale. These points may be accurately determined by some absolute method, or they may merely serve to give comparative results. Unfortunately, these pyramids afford no indications when the temperature is stationary or falling.

**Mesuré and Nouel's Pyrometric Telescope.** (*Ibid.*)—Mesuré and Nouel's pyrometric telescope gives us an immediate determination of the temperature of incandescent bodies, and is therefore much better adapted to cases where a great number of observations are to be made, and at short intervals, than Seger's. Such cases arise in the careful heating of steel. The little telescope, carried in the pocket or hung from the neck, can be used by foreman or heater at any moment.

It is based on the fact that a plate of quartz, cut at right angles to the axis, rotates the plane of polarization of polarized light to a degree nearly inversely proportional to the square of the length of the waves; and, further, on the fact that while a body at dull redness merely emits red light, as the temperature rises, the orange, yellow, green, and blue waves successively appear.

If, now, such a plate of quartz is placed between two Nicol prisms at right angles, "a ray of monochromatic light which passes the first, or polarizer, and is watched through the second, or analyzer, is not extinguished as it was before interposing the quartz. Part of the light passes the analyzer, and, to again extinguish it, we must turn one of the Nicols a certain angle," depending on the length of the waves of light, and hence on the temperature of the incandescent object which emits this light. Hence the angle through which we must turn the analyzer to extinguish the light is a measure of the temperature of the object observed.

For illustrated descriptions of different kinds of pyrometers see circular issued by Queen & Co., Philadelphia.

**The Uehling and Steinbart Pyrometer.** (For illustrated description see *Engineering*, Aug. 24, 1894.)—The action of the pyrometer is based on a principle which involves the law of the flow of gas through minute apertures in the following manner: If a closed tube or chamber be supplied with a minute inlet and a minute outlet aperture and air be caused by a constant suction to flow in through one and out through the other of these apertures, the tension in the chamber between the apertures will vary with

the difference of temperature between the inflowing and outflowing air. If the inflowing air be made to vary with the temperature to be measured, and the outflowing air be kept at a certain constant temperature, then the tension in the space or chamber between the two apertures will be an exact measure of the temperature of the inflowing air, and hence of the temperature to be measured.

In operation it is necessary that the air be sucked into it through the first minute aperture at the temperature to be measured, through the second aperture at a lower but constant temperature, and that the suction be of a constant tension. The first aperture is therefore located in the end of a platinum tube in the bulb of a porcelain tube over which the hot blast sweeps, or inserted into the pipe or chamber containing the gas whose temperature is to be ascertained.

The second aperture is located in a coupling, surrounded by boiling water, and the suction is obtained by an aspirator and regulated by a column of water of constant height.

The tension in the chamber between the apertures is indicated by a manometer.

**The Air-thermometer.** (Prof. R. C. Carpenter, *Eng'g News*, Jan. 5, 1893.)—Air is a perfect thermometric substance, and if a given mass of air be considered, the product of its pressure and volume divided by its absolute temperature is in every case constant. If the volume of air remain constant, the temperature will vary with the pressure; if the pressure remain constant the temperature will vary with the volume. As the former condition is more easily attained air-thermometers are usually constructed of constant volume, in which case the absolute temperature will vary with the pressure.

If we denote pressure by  $p$  and  $p'$ , the corresponding absolute temperatures by  $T$  and  $T'$ , we should have

$$p : p' :: T : T' \quad \text{and} \quad T' = p' \frac{T}{p}.$$

The absolute temperature  $T$  is to be considered in every case 460 higher than the thermometer-reading expressed in Fahrenheit degrees. From the form of the above equation, if the pressure  $p$  corresponding to a known absolute temperature  $T$  be known,  $T'$  can be found. The quotient  $T/p$  is a constant which may be used in all determinations with the instrument. The pressure on the instrument can be expressed in inches of mercury, and is evidently the atmospheric pressure  $b$  as shown by a barometer, plus or minus an additional amount  $h$  shown by a manometer attached to the air thermometer. That is, in general,  $p = b \pm h$ .

The temperature of 32° F. is fixed as the point of melting ice, in which case  $T = 460 + 32 = 492$ ° F. This temperature can be produced by surrounding the bulb in melting ice and leaving several minutes, so that the temperature of the confined air shall acquire that of the surrounding ice. When the air is at that temperature, note the reading of the attached manometer  $h$ , and that of a barometer; the sum will be the value of  $p$  corresponding to the absolute temperature of 492° F. The constant of the instrument,  $K = 492 \div p$ , once obtained, can be used in all future determinations.

**High Temperatures judged by Color.**—The temperature of a body can be approximately judged by the experienced eye unaided, and M. Pouillet has constructed a table, which has been generally accepted, giving the colors and their corresponding temperature as below:

	Deg. C.	Deg. F.		Deg. C.	Deg. F.
Incipient red heat..	525	977	Deep orange heat...	1100	2021
Dull red heat .....	700	1292	Clear orange heat..	1200	2192
Incipient cherry-red			White heat ....	1300	2372
heat.. .....	800	1472	Bright white heat..	1400	2552
Cherry-red heat .....	900	1652	Dazzling white heat } to 1600	1500	2732
Clear cherry-red					to
heat.....	1000	1832		1600	2912

The results obtained, however, are unsatisfactory, as much depends on the susceptibility of the retina of the observer to light as well as the degree of illumination under which the observation is made.

A bright bar of iron, slowly heated in contact with air, assumes the following tints at annexed temperatures (Claudel):

	Cent.	Fahr.		Cent.	Fahr.
Yellow at.....	225	437	Indigo at.....	288	550
Orange at.....	243	473	Blue at.....	293	559
Red at.....	265	509	Green at.....	332	630
Violet at.....	277	531	"Oxide-gray".....	400	752

**BOILING POINTS AT ATMOSPHERIC PRESSURE.**

14.7 lbs. per square inch.

Ether, sulphuric.....	100° F.	Average sea-water.....	213.2° F.
Carbon bisulphide.....	118	Saturated brine.....	226
Ammonia.....	140	Nitric acid.....	248
Chloroform.....	140	Oil of turpentine.....	315
Bromine.....	145	Phosphorus.....	554
Wood spirit.....	150	Sulphur.....	570
Alcohol.....	173	Sulphuric acid.....	590
Benzine.....	176	Linseed oil... ..	597
Water....	212	Mercury.....	676

The boiling points of liquids increase as the pressure increases. The boiling point of water at any given pressure is the same as the temperature of saturated steam of the same pressure. (See Steam.)

**MELTING-POINTS OF VARIOUS SUBSTANCES.**

The following figures are given by Clark (on the authority of Pouillet, Claudel, and Wilson), except those marked \*, which are given by Prof. Roberts-Austen in his description of the Le Chatelier pyrometer. These latter are probably the most reliable figures.

Sulphurous acid .....	- 148° F.	Alloy, 1 tin, 1 lead..	370 to 466° F.
Carbonic acid.....	- 108	Tin.....	442 to 446
Mercury.....	- 39	Cadmium.....	442
Bromine.....	+ 9.5	Bismuth.....	504 to 507
Turpentine .....	14	Lead.....	608 to 618*
Hyponitric acid.....	16	Zinc ..	680 to 779*
Ice .....	32	Antimony .....	810 to 1150
Nitro-glycerine.....	45	Aluminum.....	1157*
Tallow.....	92	Magnesium.....	1200
Phosphorus .....	112	Calcium .....	Full red heat.
Acetic acid. ....	113	Bronze ..	1692
Stearine .....	109 to 120	Silver.....	1733* to 1873
Spermaceti.....	120	Potassium sulphate.....	1859*
Margaric acid .....	131 to 140	Gold .....	1913* to 2282
Potassium .....	136 to 144	Copper .....	1929* to 1996
Wax.....	142 to 154	Cast iron, white... ..	1922 to 2075*
Stearic acid ...	158	“ gray	2012 to 2786 2228*
Sodium .....	194 to 208	Steel.....	2372 to 2532
Alloy, 3 lead, 2 tin, 5 bismuth	199	“ hard .....	2570*; mild, 2687*
Iodine.....	225	Wrought iron.....	2732 to 2912
Sulphur .....	239	Palladium ..	2732*
Alloy, 1½ tin, 1 lead.....	334	Platinum.....	3227*

For melting-point of fusible alloys, see Alloys.

Cobalt, nickel, and manganese, fusible in highest heat of a forge. Tungsten and chromium, not fusible in forge, but soften and agglomerate. Platinum and iridium, fusible only before the oxyhydrogen blowpipe.

**QUANTITATIVE MEASUREMENT OF HEAT.**

**Unit of Heat.**—The British unit of heat, or British thermal unit (B. T. U.), is that quantity of heat which is required to raise the temperature of 1 lb. of pure water 1° Fahr., at or near 39°.1 F., the temperature of maximum density of water.

The French thermal unit, or *calorie*, is that quantity of heat which is required to raise the temperature of 1 kilogramme of pure water 1° Cent., at or about 4° C., which is equivalent to 39°.1 F.

1 French calorie = 3.968 British thermal units; 1 B. T. U. = .252 calorie. The “pound calorie” is sometimes used by English writers; it is the quan-

tity of heat required to raise the temperature of 1 lb. of water 1° C. 1 lb. calorie =  $9/5$  B.T.U. = 0.4536 calorie. The heat of combustion of carbon, to CO<sub>2</sub>, is said to be 8080 calories. This figure is used either for French calories or for pound calories, as it is the number of pounds of water that can be raised 1° C. by the complete combustion of 1 lb. of carbon, or the number of kilogrammes of water that can be raised 1° C. by the combustion of 1 kilo. of carbon; assuming in each case that all the heat generated is transferred to the water.

**The Mechanical Equivalent of Heat** is the number of foot-pounds of mechanical energy equivalent to one British thermal unit, heat and mechanical energy being mutually convertible. Joule's experiments, 1843-50, gave the figure 772, which is known as Joule's equivalent. More recent experiments by Prof. Rowland (*Proc. Am. Acad. Arts and Sciences*, 1880; see also *Wood's Thermodynamics*) give higher figures, and the most probable average is now considered to be 778.

1 heat-unit is equivalent to 778 ft.-lbs. of energy. 1 ft. lb. =  $1/778 = .0012852$  heat-units. 1 horse-power = 33,000 ft.-lbs. per minute = 2545 heat-units per hour = 42.416 + per minute = .70694 per second. 1 lb. carbon burned to CO<sub>2</sub> = 14,544 heat-units. 1 lb. C. per H.P. per hour =  $2545 \div 14544 = 17\frac{1}{2}\%$  efficiency (.174986).

### Heat of Combustion of Various Substances in Oxygen.

	{ 9,915	17,847	Favre and Silbermann.

In burning 1 pound of hydrogen with 8 pounds of oxygen to form 9 pounds of water, the units of heat evolved are 62,032 (Favre and S.); but if the resulting product is not cooled to the initial temperature of the gases, part of the heat is rendered latent in the steam. The total heat of 1 lb. of steam at 212° F. is 1146.1 heat-units above that of water at 32°, and  $9 \times 1146.1 = 10,315$  heat-units, which deducted from 62,032 gives 51,717 as the heat evolved by the combustion of 1 lb. of hydrogen and 8 lbs. of oxygen at 32° F. to form steam at 212° F.

By the decomposition of a chemical compound as much heat is absorbed or rendered latent as was evolved when the compound was formed. If 1 lb. of carbon is burned to CO<sub>2</sub>, generating 14,544 B.T.U., and the CO<sub>2</sub> thus formed is immediately reduced to CO in the presence of glowing carbon, by the reaction  $CO_2 + C = 2CO$ , the result is the same as if the 2 lbs. C had been burned directly to 2CO, generating  $2 \times 4451 = 8902$  heat-units; consequently  $14,544 - 8902 = 5642$  heat-units have disappeared or become latent, and the

“unburning” of CO<sub>2</sub> to CO is thus a cooling operation. (For heats of combustion of various fuels, see Fuel.)

**SPECIFIC HEAT.**

**Thermal Capacity.**—The thermal capacity of a body is the quantity of heat required to raise its temperature one degree. The ratio of the heat required to raise the temperature of a certain weight of a given substance one degree to that required to raise the temperature of the same weight of water one degree from the temperature of maximum density 39.1 is commonly called the *specific heat* of the substance. Some writers object to the term as being an inaccurate use of the words “specific” and “heat.” A more correct name would be “coefficient of thermal capacity.”

**Determination of Specific Heat.**—*Method by Mixture.*—The body whose specific heat is to be determined is raised to a known temperature, and is then immersed in a mass of liquid of which the weight, specific heat, and temperature are known. When both the body and the liquid have attained the same temperature, this is carefully ascertained.

Now the quantity of heat lost by the body is the same as the quantity of heat absorbed by the liquid.

Let *c*, *w*, and *t* be the specific heat, weight, and temperature of the hot body, and *c'*, *w'*, and *t'* of the liquid. Let *T* be the temperature the mixture assumes.

Then, by the definition of specific heat,  $c \times w \times (t - T) =$  heat-units lost by the hot body, and  $c' \times w' \times (T - t') =$  heat-units gained by the cold liquid. If there is no heat lost by radiation or conduction, these must be equal, and

$$cw(t - T) = c'w'(T - t') \quad \text{or} \quad c = \frac{c'w'(T - t')}{w(t - T)}$$

**Specific Heats of Various Substances.**

The specific heats of substances, as given by different authorities, show considerable lack of agreement, especially in the case of gases.

The following tables give the mean specific heats of the substances named according to Regnault. (From Rontgen's Thermodynamics, p. 134.) These specific heats are average values, taken at temperatures which usually come under observation in technical application. The actual specific heats of all substances, in the solid or liquid state, increase slowly as the body expands or as the temperature rises. It is probable that the specific heat of a body when liquid is greater than when solid. For many bodies this has been verified by experiment.

“ 0° C. “ 200° C.....	0.23751

Hanssen uses 0.1686 for the specific heat of air at constant volume. The value of this constant has never been found to any degree of accuracy by direct experiment. Prof. Wood gives  $0.2375 \div 1.406 = 0.1689$ . The ratio of

the specific heat of a fixed gas at constant pressure to the sp. ht. at constant volume is given as follows by different writers (*Eng'g*, July 12, 1889): Regnault, 1.3953; Moll and Beck, 1.4085; Szathmari, 1.4037; J. Macfarlane Gray, 1.4. The first three are obtained from the velocity of sound in air. The fourth is derived from theory. Prof. Wood says: The value of the ratio for air, as found in the days of La Place, was 1.41, and we have  $0.2377 \div 1.41 = 0.1686$ , the value used by Clausius, Hanssen, and many others. But this ratio is not definitely known. Rankine in his later writings used 1.408, and Tait in a recent work gives 1.404, while some experiments gives less than 1.4 and others more than 1.41. Prof. Wood uses 1.406.

**Specific Heat of Gases.**—Experiments by Mallard and Le Chatelier indicate a continuous increase in the specific heat at constant volume of steam, CO<sub>2</sub>, and even of the perfect gases, with rise of temperature. The variation is inappreciable at 100° C., but increases rapidly at the high temperatures of the gas-engine cylinder. (Robinson's Gas and Petroleum Engines.)

**Specific Heat and Latent Heat of Fusion of Iron and Steel.** (H. H. Campbell, Trans. A. I. M. E., xix. 181.)

		Åkerman.	Troilius.
Specific heat pig iron,	0 to 1200° C.....	0.16	....
“ “ “	1200 to 1800° C.....	0.21	....
“ “ “	0 to 1500° C.....	....	0.18
“ “ “	1500 to 1800° C.....	....	0.20

Calculating by both sets of data we have :

	Åkerman.	Troilius.
Heating from 0 to 1800° C..	318	330 calories per kilo.
Hence probable value is about.....	325	calories per kilo.
Specific heat, steel (probably high carbon)....	(Troilius).....	.1175
“ “ soft iron.....	“ .....	.1081
Hence probable value solid rail steel.....	“ .....	.1125

	Åkerman.	Troilius.
Latent heat of fusion, pig iron, calories per kilo..	46	..
“ “ “ gray pig.....	“ .....	33
“ “ “ white pig .....	“ .....	23

From which we may assume that the truth is about : Steel, 20 ; pig iron, 30.

**EXPANSION BY HEAT.**

In the centigrade scale the coefficient of expansion of air per degree is  $0.003665 = 1/273$ ; that is, the pressure being constant, the volume of a perfect gas increases  $1/273$  of its volume at 0° C. for every increase in temperature of 1° C. In Fahrenheit units it increases  $1/491.2 = .002036$  of its volume at 32° F. for every increase of 1° F.

**Expansion of Gases by Heat from 32° to 212° F. (Regnault.)**

	Increase in Volume, Pressure Constant. Volume at 32° Fahr. = 1.0, for		Increase in Pressure, Volume Constant. Pressure at 32° Fahr. = 1.0, for	
	100° C.	1° F.	100° C.	1° F.

Cubical expansion, or expansion of volume = linear expansion  $\times$  3.

**Absolute Temperature—Absolute Zero.**—The absolute zero of a gas is a theoretical consequence of the law of expansion by heat, assuming that it is possible to continue the cooling of a perfect gas until its volume is diminished to nothing.

If the volume of a perfect gas increases  $1/273$  of its volume at  $0^\circ \text{C}$ . for every increase of temperature of  $1^\circ \text{C}$ ., and decreases  $1/273$  of its volume for every decrease of temperature of  $1^\circ \text{C}$ ., then at  $-273^\circ \text{C}$ . the volume of the imaginary gas would be reduced to nothing. This point  $-273^\circ \text{C}$ ., or  $491.2^\circ \text{F}$ . below the melting-point of ice on the air thermometer, or  $492.66^\circ \text{F}$ . below on a perfect gas thermometer =  $-459.2^\circ \text{F}$ . (or  $-460.66^\circ$ ), is called the absolute zero; and absolute temperatures are temperatures measured, on either the Fahrenheit or centigrade scale, from this zero. The freezing point,  $32^\circ \text{F}$ ., corresponds to  $491.2^\circ \text{F}$ . absolute. If  $p_0$  be the pressure and  $v_0$  the volume of a gas at the temperature of  $32^\circ \text{F}$ . =  $491.2^\circ$  on the absolute scale =  $T_0$ , and  $p$  the pressure, and  $v$  the volume of the same quantity of gas at any other absolute temperature  $T$ , then

$$\frac{pv}{p_0v_0} = \frac{T}{T_0} = \frac{t + 459.2}{491.2}; \quad \frac{pv}{T} = \frac{p_0v_0}{T_0}.$$

The value of  $p_0v_0 \div T_0$  for air is  $53.37$ , and  $pv = 53.37T$ , calculated as follows by Prof. Wood:

A cubic foot of dry air at  $32^\circ \text{F}$ . at the sea-level weighs  $0.080728 \text{ lb}$ . The volume of one pound is  $v_0 = \frac{1}{.080728} = 12.387$  cubic feet. The pressure per square foot is  $2116.2 \text{ lbs}$ .

$$\frac{p_0v_0}{T_0} = \frac{2116.2 \times 12.387}{491.13} = \frac{26214}{491.13} = 53.37.$$

The figure  $491.13$  is the number of degrees that the absolute zero is below the melting-point of ice, by the air thermometer. On the absolute scale, whose divisions would be indicated by a perfect gas thermometer, the calculated value approximately is  $492.66$ , which would make  $pv = 53.21T$ . Prof. Thomson considers that  $-273.1^\circ \text{C}$ ., =  $-459.4^\circ \text{F}$ ., is the most probable value of the absolute zero. See *Heat in Encyc. Brit.*

**Expansion of Liquids from  $32^\circ$  to  $212^\circ \text{F}$ .**—Apparent expansion in glass (Clark). Volume at  $212^\circ$ , volume at  $32^\circ$  being 1:

For air at various temperatures, see Air.

**LATENT HEATS OF FUSION AND EVAPORATION.**

**Latent Heat** means a quantity of heat which has disappeared, having been employed to produce some change other than elevation of temperature. By exactly reversing that change, the quantity of heat which has disappeared is reproduced. Maxwell defines it as the quantity of heat which must be communicated to a body in a given state in order to convert it into another state without changing its temperature.

**Latent Heat of Fusion.**—When a body passes from the solid to the liquid state, its temperature remains stationary, or nearly stationary, at a certain melting point during the whole operation of melting; and in order to make that operation go on, a quantity of heat must be transferred to the substance melted, being a certain amount for each unit of weight of the substance. This quantity is called the latent heat of fusion.

When a body passes from the liquid to the solid state, its temperature remains stationary or nearly stationary during the whole operation of freezing; a quantity of heat equal to the latent heat of fusion is produced in the body and rejected into the atmosphere or other surrounding bodies.

The following are examples in British thermal units per pound, as given in Landolt & Börnstein's *Physikalische-Chemische Tabellen* (Berlin, 1894).

Substances.	Latent Heat of Fusion.	Substances.	Latent Heat of Fusion.
Bismuth...	22.75	Silver.....	37.93
Cast Iron, gray... ..	41.4	Beeswax.....	76.14
Cast Iron, white.....	59.4	Paraffine.....	63.27
Lead.....	9.66	Spermaceti.....	66.56
Tin.....	25.65	Phosphorus.....	9.06
Zinc.....	50.63	Sulphur.....	16.86

Prof. Wood considers 144 heat units as the most reliable value for the latent heat of fusion of ice. Person gives 142.65.

**Latent Heat of Evaporation.**—When a body passes from the solid or liquid to the gaseous state, its temperature during the operation remains stationary at a certain boiling point, depending on the pressure of the vapor produced; and in order to make the evaporation go on, a quantity of heat must be transferred to the substance evaporated, whose amount for each unit of weight of the substance evaporated depends on the temperature. That heat does not raise the temperature of the substance, but disappears in causing it to assume the gaseous state, and it is called the latent heat of evaporation.

When a body passes from the gaseous state to the liquid or solid state, its temperature remains stationary, during that operation, at the boiling-point corresponding to the pressure of the vapor: a quantity of heat equal to the latent heat of evaporation at that temperature is produced in the body; and in order that the operation of condensation may go on, that heat must be transferred from the body condensed to some other body.

The following are examples of the latent heat of evaporation in British thermal units, of one pound of certain substances, when the pressure of the vapor is one atmosphere of 14.7 lbs. on the square inch:

Substance.	Boiling-point under one atm. Fahr.	Latent Heat in British units.
Water . . . . .	212.0	965.7 (Regnault.)
Alcohol . . . . .	172.2	364.3 (Andrews.)
Ether . . . . .	95.0	162.8 “
Bisulphide of carbon . . . . .	114.8	156.0 “

The latent heat of evaporation of water at a series of boiling-points extending from a few degrees below its freezing-point up to about 375 degrees Fahrenheit has been determined experimentally by M. Regnault. The results of those experiments are represented approximately by the formula. in British thermal units per pound,

$$l \text{ nearly} = 1091.7 - 0.7(t - 32^\circ) = 965.7 - 0.7(t - 212^\circ).$$

**The Total Heat of Evaporation** is the sum of the heat which disappears in evaporating one pound of a given substance at a given temperature (or latent heat of evaporation) and of the heat required to raise its temperature, before evaporation, from some fixed temperature up to the temperature of evaporation. The latter part of the total heat is called the sensible heat.

In the case of water, the experiments of M. Regnault show that the total heat of steam from the temperature of melting ice increases at a uniform rate as the temperature of evaporation rises. The following is the formula in British thermal units per pound:

$$h = 1091.7 + 0.305(t - 32^\circ).$$

For the total heat, latent heat, etc., of steam at different pressures, see table of the Properties of Saturated Steam. For tables of total heat, latent heat, and other properties of steams of ether, alcohol, acetone, chloroform, chloride of carbon, and bisulphide of carbon, see Rontgen's Thermodynamics (Dubois's translation.) For ammonia and sulphur dioxide, see Wood's Thermodynamics; also, tables under Refrigerating Machinery, in this book.

## EVAPORATION AND DRYING.

In evaporation, the formation of vapor takes place on the surface; in boiling, within the liquid: the former is a slow, the latter a quick, method of evaporation.

If we bring an open vessel with water under the receiver of an air-pump and exhaust the air the water in the vessel will commence to boil, and if we keep up the vacuum the water will actually boil near its freezing-point. The formation of steam in this case is due to the heat which the water takes out of the surroundings.

Steam formed under pressure has the same temperature as the liquid in which it was formed, provided the steam is kept under the same pressure.

By properly cooling the rising steam from boiling water, as in the multiple-effect evaporating systems, we can regulate the pressure so that the water boils at low temperatures.

**Evaporation of Water in Reservoirs.**—Experiments at the Mount Hope Reservoir, Rochester, N. Y., in 1891, gave the following results:

	July.	Aug.	Sept.	Oct.
Mean temperature of air in shade.....	70.5	70.3	68.7	53.3
“ “ “ water in reservoir.....	68.2	70.2	66.1	54.4
“ humidity of air, per cent... ..	67.0	74.6	75.2	74.7
Evaporation in inches during month.....	5.59	4.93	4.05	3.23
Rainfall in inches during month.....	3.44	2.95	1.44	2.16

**Evaporation of Water from Open Channels.** (Flynn's Irrigation Canals and Flow of Water.)—Experiments from 1881 to 1885 in Tulare County, California, showed an evaporation from a pan in the river equal to an average depth of one eighth of an inch per day throughout the year.

When the pan was in the air the average evaporation was less than 3/16 of an inch per day. The average for the month of August was 1/3 inch per day, and for March and April 1/12 of an inch per day. Experiments in Colorado show that evaporation ranges from .088 to .16 of an inch per day during the irrigating season.

In Northern Italy the evaporation was from 1/12 to 1/9 inch per day, while in the south, under the influence of hot winds, it was from 1/6 to 1/5 inch per day.

In the hot season in Northern India, with a decidedly hot wind blowing, the average evaporation was 1/2 inch per day. The evaporation increases with the temperature of the water.

**Evaporation by the Multiple System.**—A multiple effect is a series of evaporating vessels each having a steam chamber, so connected that the heat of the steam or vapor produced in the first vessel heats the second, the vapor or steam produced in the second heats the third, and so on. The vapor from the last vessel is condensed in a condenser. Three vessels are generally used, in which case the apparatus is called a *Triple Effect*. In evaporating in a triple effect the vacuum is graduated so that the liquid is boiled at a constant and low temperature.

**Resistance to Boiling.—Brine.** (Rankine.)—The presence in a liquid of a substance dissolved in it (as salt in water) resists ebullition, and raises the temperature at which the liquid boils, under a given pressure; but unless the dissolved substance enters into the composition of the vapor, the relation between the temperature and pressure of saturation of the vapor remains unchanged. A resistance to ebullition is also offered by a vessel of a material which attracts the liquid (as when water boils in a glass vessel), and the boiling takes place by starts. To avoid the errors which causes of this kind produce in the measurement of boiling-points, it is advisable to place the thermometer, not in the liquid, but in the vapor, which shows the true boiling-point, freed from the disturbing effect of the attractive nature of the vessel. The boiling-point of saturated brine under one atmosphere is 226° Fahr., and that of weaker brine is higher than the boiling-point of pure water by 1.2° Fahr., for each 1/32 of salt that the water contains. Average sea-water contains 1/32; and the brine in marine boilers is not suffered to contain more than from 2/32 to 3/32.

**Methods of Evaporation Employed in the Manufacture of Salt.** (F. E. Engelhardt, Chemist Onondaga Salt Springs; Report for 1889.)—1. Solar heat—solar evaporation. 2. Direct fire, applied to the heating surface of the vessels containing brine—kettle and pan methods. 3. The steam-grainer system—steam-pans, steam-kettles, etc. 4. Use of steam and a reduction of the atmospheric pressure over the boiling brine—vacuum system.

When a saturated salt solution boils, it is immaterial whether it is done under ordinary atmospheric pressure at 228° F., or under four atmospheres with a temperature of 320° F., or in a vacuum under 1/10 atmosphere, the result will always be a fine-grained salt.

The fuel consumption is stated to be as follows: By the kettle method, 40 to 45 bu. of salt evaporated per ton of fuel, anthracite dust burned on perforated grates; evaporation, 5.53 lbs. of water per pound of coal. By the pan method, 70 to 75 bu. per ton of fuel. By vacuum pans, single effect, 86 bu. per ton of anthracite dust (2000 lbs.). With a double effect nearly double that amount can be produced.

**Solubility of Common Salt in Pure Water. (Andræ.)**

Temp. of brine, F.....	32	50	86	104	140	176
100 parts water dissolve parts....	35.63	35.69	36.03	36.32	37.06	38.00
100 parts brine contain salt.....	26.27	26.30	26.49	26.64	27.04	27.54

According to Poggial, 100 parts of water dissolve at 229.66° F., 40.35 parts of salt, or in per cent of brine, 28.749. Gay Lussac found that at 229.72° F., 100 parts of pure water would dissolve 40.38 parts of salt, in per cent of brine, 28.764 parts.

The solubility of salt at 229° F. is only 2.5% greater than at 32°. Hence we cannot, as in the case of alum, separate the salt from the water by allowing a saturated solution at the boiling point to cool to a lower temperature.

**Solubility of Sulphate of Lime in Pure Water. (Marignac.)**

Temperature F. degrees.	32	64.5	89.6	100.4	105.8	127.4	186.8	212
Parts water to dissolve } 1 part gypsum	415	386	371	368	370	375	417	452
Parts water to dissolve 1 } part anhydrous CaSO <sub>4</sub>	525	488	470	466	468	474	528	572

In salt brine sulphate of lime is much more soluble than in pure water. In the evaporation of salt brine the accumulation of sulphate of lime tends to stop the operation, and it must be removed from the pans to avoid waste of fuel.

The average strength of brine in the New York salt districts in 1889 was 69.38 degrees of the salinometer.

**Strength of Salt Brines.**—The following table is condensed from one given in U. S. Mineral Resources for 1888, on the authority of Dr. Englehardt.

**Relations between Salinometer Strength, Specific Gravity, Solid Contents, etc., of Brines of Different Strengths.**

Salinometer, degrees.	Baumé, degrees.	Specific gravity.	Per cent of salt.	Weight of a gallon of this brine in pounds.	Pounds of salt in a gallon of brine of 31 cubic inches.	Gallons of brine required for a bushel of salt.	Pounds of water to be evaporated to produce a bushel of salt.	Lbs. of coal required to produce a bushel of salt, 1 lb. coal evaporating 6 lbs. of water.	Bushels of salt that can be made with a ton of coal of 2000 pounds.

**Concentration of Sugar Solutions.\*** (From "Heating and Concentrating Liquids by Steam," by John G. Hudson; *The Engineer*, June 13, 1890.)—In the early stages of the process, when the liquor is of low density, the evaporative duty will be high, say two to three (British) gallons per square foot of heating surface with 10 lbs. steam pressure, but will gradually fall to an almost nominal amount as the final stage is approached. As a generally safe basis for designing, Mr. Hudson takes an evaporation of one gallon per hour for each square foot of gross heating surface, with steam of the pressure of about 10 lbs.

As examples of the evaporative duty of a vacuum pan when performing the earlier stages of concentration, during which all the heating surface can be employed, he gives the following:

**COIL VACUUM PAN.**— $4\frac{3}{4}$  in. copper coils, 528 square feet of surface; steam in coils, 15 lbs.; temperature in pan,  $141^{\circ}$  to  $148^{\circ}$ ; density of feed,  $25^{\circ}$  Beaumé, and concentrated to  $31^{\circ}$  Beaumé.

*First Trial.*—Evaporation at the rate of 2000 gallons per hour = 3.8 gallons per square foot; transmission, 376 units per degree of difference of temperature.

*Second Trial.*—Evaporation at the rate of 1503 gallons per hour = 2.8 gallons per square foot; transmission, 265 units per degree.

As regards the total time needed to work up a charge of massecuite from liquor of a given density, the following figures, obtained by plotting the results from a large number of pans, form a guide to practical working. The pans were all of the coil type, some with and some without jackets, the gross heating surface probably averaging, and not greatly differing from, .25 square foot per gallon capacity, and the steam pressure 10 lbs. per square inch. Both plantation and refining pans are included, making various grades of sugar:

	Density of Feed (degs. Beaumé).				
	$10^{\circ}$	$15^{\circ}$	$20^{\circ}$	$25^{\circ}$	$30^{\circ}$
Evaporation required per gallon massecuite discharged.....	6.123	3.6	2.26	1.5	.97
Average working hours required per charge .....	12.	9.	$6\frac{1}{2}$	5.	4.
Equivalent average evaporation per hour per square foot of gross surface, assuming .25 sq. ft. per gallon capacity..	2.04	1.6	1.39	1.2	.97
Fastest working hours required per charge .....	8.5	5.5	3.8	2.75	2.0
Equivalent average evaporation per hour per square foot.....	2.88	2.6	2.38	2.18	1.9

The quantity of heating steam needed is practically the same in vacuum as in open pans. The advantages proper to the vacuum system are primarily the reduced temperature of boiling, and incidentally the possibility of using heating steam of low pressure.

In a solution of sugar in water, each pound of sugar adds to the volume of the water to the extent of .061 gallon at a low density to .0638 gallon at high densities.

**A Method of Evaporating by Exhaust Steam** is described by Albert Stearns in *Trans. A. S. M. E.*, vol. viii. A pan  $17' 6'' \times 11' \times 1' 6''$ , fitted with cast-iron condensing pipes of about 250 sq. ft. of surface, evaporated 120 gallons per hour from clear water, condensing only about one half of the steam supplied by a plain slide-valve engine of  $14'' \times 32''$  cylinder, making 65 revs. per min., cutting off about two thirds stroke, with steam at 75 lbs. boiler pressure.

It was found that keeping the pan-room warm and letting only sufficient air in to carry the vapor up out of a ventilator adds to its efficiency, as the average temperature of the water in the pan was only about  $165^{\circ}$  F.

Experiments were made with coils of pipe in a small pan, first with no agitator, then with one having straight blades, and lastly with troughed blades; the evaporative results being about the proportions of one, two, and three respectively.

In evaporating liquors whose boiling point is  $220^{\circ}$  F., or much above that of water, it is found that exhaust steam can do but little more than bring them up to saturation strength, but on weak liquors, syrups, glues, etc., it should be very useful.

\* For other sugar data see Bagasse as Fuel, under *Fuel*.

**Drying in Vacuum.**—An apparatus for drying grain and other substances in vacuum is described by Mr. Emil Passburg in Proc. Inst. Mech. Engrs., 1889. The three essential requirements for a successful and economical process of drying are: 1. Cheap evaporation of the moisture; 2. Quick drying at a low temperature; 3. Large capacity of the apparatus employed.

The removal of the moisture can be effected in either of two ways: either by slow evaporation, or by quick evaporation—that is, by boiling.

*Slow Evaporation.*—The principal idea carried into practice in machines acting by slow evaporation is to bring the wet substance repeatedly into contact with the inner surfaces of the apparatus, which are heated by steam, while at the same time a current of hot air is also passing through the substances for carrying off the moisture. This method requires much heat, because the hot-air current has to move at a considerable speed in order to shorten the drying process as much as possible; consequently a great quantity of heated air passes through and escapes unused. As a carrier of moisture hot air cannot in practice be charged beyond half its full saturation; and it is in fact considered a satisfactory result if even this proportion be attained. A great amount of heat is here produced which is not used; while, with scarcely half the cost for fuel, a much quicker removal of the water is obtained by heating it to the boiling point.

*Quick Evaporation by Boiling.*—This does not take place until the water is brought up to the boiling point and kept there, namely, 212° F., under atmospheric pressure. The vapor generated then escapes freely. Liquids are easily evaporated in this way, because by their motion consequent on boiling the heat is continuously conveyed from the heating surfaces through the liquid, but it is different with solid substances, and many more difficulties have to be overcome, because convection of the heat ceases entirely in solids. The substance remains motionless, and consequently a much greater quantity of heat is required than with liquids for obtaining the same results.

*Evaporation in Vacuum.*—All the foregoing disadvantages are avoided if the boiling-point of water is lowered, that is, if the evaporation is carried out under vacuum.

This plan has been successfully applied in Mr. Passburg's vacuum drying apparatus, which is designed to evaporate large quantities of water contained in solid substances.

The drying apparatus consists of a top horizontal cylinder, surmounted by a charging vessel at one end, and a bottom horizontal cylinder with a discharging vessel beneath it at the same end. Both cylinders are encased in steam-jackets heated by exhaust steam. In the top cylinder works a revolving cast-iron screw with hollow blades, which is also heated by exhaust steam. The bottom cylinder contains a revolving drum of tubes, consisting of one large central tube surrounded by 24 smaller ones, all fixed in tube-plates at both ends; this drum is heated by live steam direct from the boiler. The substance to be dried is fed into the charging vessel through two man-holes, and is carried along the top cylinder by the screw creeper to the back end, where it drops through a valve into the bottom cylinder, in which it is lifted by blades attached to the drum and travels forwards in the reverse direction; from the front end of the bottom cylinder it falls into a discharging vessel through another valve, having by this time become dried. The vapor arising during the process is carried off by an air-pump, through a dome and air-valve on the top of the upper cylinder, and also through a throttle-valve on the top of the lower cylinder; both of these valves are supplied with strainers.

As soon as the discharging vessel is filled with dried material the valve connecting it with the bottom cylinder is shut, and the dried charge taken out without impairing the vacuum in the apparatus. When the charging vessel requires replenishing, the intermediate valve between the two cylinders is shut, and the charging vessel filled with a fresh supply of wet material; the vacuum still remains unimpaired in the bottom cylinder, and has to be restored only in the top cylinder after the charging vessel has been closed again.

In this vacuum the boiling-point of the water contained in the wet material is brought down as low as 110° F. The difference between this temperature and that of the heating surfaces is amply sufficient for obtaining good results from the employment of exhaust steam for heating all the surfaces except the revolving drum of tubes. The water contained in the solid substance to be dried evaporates as soon as the latter is heated to about 110° F.;

and as long as there is any moisture to be removed the solid substance is not heated above this temperature.

Wet grains from a brewery or distillery, containing from 75% to 78% of water, have by this drying process been converted in some localities from a worthless incumbrance into a valuable food-stuff. The water is removed by evaporation only, no previous mechanical pressing being resorted to.

At Messrs. Guinness's brewery in Dublin two of these machines are employed. In each of these the top cylinder is 20' 4'' long and 2' 8'' diam., and the screw working inside it makes 7 revs. per min.; the bottom cylinder is 19' 2'' long and 5' 4'' diam., and the drum of the tubes inside it makes 5 revs. per min. The drying surfaces of the two cylinders amount together to a total area of about 1000 sq. ft., of which about 40% is heated by exhaust steam direct from the boiler. There is only one air-pump, which is made large enough for three machines; it is horizontal, and has only one air-cylinder, which is double-acting, 17 $\frac{3}{4}$  in. diam. and 17 $\frac{3}{4}$  in. stroke; and it is driven at about 45 revs. per min. As the result of about eight months' experience, the two machines have been drying the wet grains from about 500 cwt. of malt per day of 24 hours.

Roughly speaking, 3 cwt. of malt gave 4 cwt. of wet grains, and the latter yield 1 cwt. of dried grains; 500 cwt. of malt will therefore yield about 670 cwt. of wet grains, or 335 cwt. per machine. The quantity of water to be evaporated from the wet grains is from 75% to 78% of their total weight, or say about 512 cwt. altogether, being 256 cwt. per machine.

### RADIATION OF HEAT.

Radiation of heat takes place between bodies at all distances apart, and follows the laws for the radiation of light.

The heat rays proceed in straight lines, and the intensity of the rays radiated from any one source varies inversely as the square of their distance from the source.

This statement has been erroneously interpreted by some writers, who have assumed from it that a boiler placed two feet above a fire would receive by radiation only one fourth as much heat as if it were only one foot above. In the case of boiler furnaces the side walls reflect those rays that are received at an angle—following the law of optics, that the angle of incidence is equal to the angle of reflection,—with the result that the intensity of heat two feet above the fire is practically the same as at one foot above, instead of only one-fourth as much.

The rate at which a hotter body radiates heat, and a colder body absorbs heat, depends upon the state of the surfaces of the bodies as well as on their temperatures. The rate of radiation and of absorption are increased by darkness and roughness of the surfaces of the bodies, and diminished by smoothness and polish. For this reason the covering of steam pipes and boilers should be smooth and of a light color: uncovered pipes and steam-cylinder covers should be polished.

The quantity of heat radiated by a body is also a measure of its heat-absorbing power, under the same circumstances. When a polished body is struck by a ray of heat, it absorbs part of the heat and reflects the rest. The reflecting power of a body is therefore the complement of its absorbing power, which latter is the same as its radiating power.

The relative radiating and reflecting power of different bodies has been determined by experiment, as shown in the table below, but as far as quantities of heat are concerned, says Prof. Trowbridge (Johnson's Cyclopædia, art. Heat), it is doubtful whether anything further than the said relative determinations can, in the present state of our knowledge, be depended upon, the actual or absolute quantities for different temperatures being still uncertain. The authorities do not even agree on the relative radiating powers. Thus, Leslie gives for tin plate, gold, silver, and copper the figure 12, which differs considerably from the figures in the table below, given by Clark, stated to be on the authority of Leslie, De La Provostaye and Desains, and Melloni,

**Relative Radiating and Reflecting Power of Different Substances.**

	Radiating or Absorbing Power.	Reflecting Power.		Radiating or Absorbing Power.	Reflecting Power.
Lampblack .....	100	0	Zinc, polished. ....	19	81
Water .....	100	0	Steel, polished.....	17	83
Carbonate of lead...	100	0	Platinum, polished..	24	76
Writing-paper.....	98	2	“ in sheet ..	17	83
Ivory, jet, marble...	93 to 98	7 to 2	Tin .. .. .	15	85
Ordinary glass.....	90	10	Brass, cast, dead		
Ice.....	85	15	polished.....	11	89
Gum lac.....	72	28	Brass, bright pol-		
Silver-leaf on glass..	27	73	ished.....	7	93
Cast iron, bright pol-			Copper, varnished ..	14	86
ished.....	25	75	“ hammered..	7	93
Mercury, about.....	23	77	Gold, plated.....	5	95
Wrought iron, pol-			“ on polished		
ished. ....	23	77	steel.....	3	97
			Silver, polished		
			bright.....	3	97

Experiments of Dr. A. M. Mayer give the following: The relative radiations from a cube of cast iron, having faces rough, as from the foundry, planed, “drawfiled,” and polished, and from the same surfaces oiled, are as below (Prof. Thurston, in Trans. A. S. M. E., vol. xvi.):

Surface.	Oiled.	Dry.
Rough.....	100	100
Planed.....	60	32
Drawfiled.....	49	20
Polished.....	45	18

It here appears that the oiling of smoothly polished castings, as of cylinder-heads of steam-engines, more than doubles the loss of heat by radiation, while it does not seriously affect rough castings.

**CONDUCTION AND CONVECTION OF HEAT.**

**Conduction** is the transfer of heat between two bodies or parts of a body which touch each other. Internal conduction takes place between the parts of one continuous body, and external conduction through the surface of contact of a pair of distinct bodies.

The rate at which conduction, whether internal or external, goes on, being proportional to the area of the section or surface through which it takes place, may be expressed in thermal units per square foot of area per hour

**Internal Conduction** varies with the *heat conductivity*, which depends upon the nature of the substance, and is directly proportional to the difference between the temperatures of the two faces of a layer, and inversely as its thickness. The reciprocal of the conductivity is called the *internal thermal resistance* of the substance. If *r* represents this resistance, *x* the thickness of the layer in inches, *T'* and *T* the temperatures on the two faces, and *q* the quantity in thermal units transmitted per hour per square

foot of area,  $q = \frac{T' - T}{rx}$ . (Rankine.)

Péclet gives the following values of *r* :

Gold, platinum, silver.....	0.0016	Lead.....	0.0090
Copper.....	0.0018	Marble.....	0.0716
Iron.....	0.0043	Brick.....	0.1500

		“ with .25% of arsenic.....	771

**The Rate of External Conduction** through the bounding surface between a solid body and a fluid is approximately proportional to the difference of temperature, when that is small ; but when that difference is considerable the rate of conduction increases faster than the simple ratio of that difference. (Rankine.)

If  $r$ , as before, is the coefficient of internal thermal resistance,  $e$  and  $e'$  the coefficient of external resistance of the two surfaces,  $x$  the thickness of the plate, and  $T'$  and  $T$  the temperatures of the two fluids in contact with the two surfaces, the rate of conduction is  $q = \frac{T' - T}{e + e' + rx}$ . According to

Peclet,  $e + e' = \frac{1}{A[1 + B(T' - T)]}$ , in which the constants  $A$  and  $B$  have the following values :

$B$ for polished metallic surfaces.....	.0028
$B$ for rough metallic surfaces and for non-metallic surfaces..	.0037
$A$ for polished metals, about.....	.90
$A$ for glassy and varnished surfaces.....	1.34
$A$ for dull metallic surfaces.....	1.58
$A$ for lamp-black.....	1.78

When a metal plate has a liquid at each side of it, it appears from experiments by Peclet that  $B = .058$ ,  $A = 8.8$ .

The results of experiments on the evaporative power of boilers agree very well with the following approximate formula for the thermal resistance of boiler plates and tubes :

$$e + e' = \frac{a}{(T' - T)},$$

which gives for the rate of conduction, per square foot of surface per hour,

$$q = \frac{(T' - T)^2}{a}.$$

This formula is proposed by Rankine as a rough approximation, near enough to the truth for its purpose. The value of  $a$  lies between 160 and 200.

**Convection**, or carrying of heat, means the transfer and diffusion of the heat in a fluid mass by means of the motion of the particles of that mass.

The conduction, properly so called, of heat through a stagnant mass of fluid is very slow in liquids, and almost, if not wholly, inappreciable in gases. It is only by the continual circulation and mixture of the particles of the fluid that uniformity of temperature can be maintained in the fluid mass, or heat transferred between the fluid mass and a solid body.

The free circulation of each of the fluids which touch the side of a solid plate is a necessary condition of the correctness of Rankine's formulæ for the conduction of heat through that plate; and in these formulæ it is im-

plied that the circulation of each of the fluids by currents and eddies is such as to prevent any considerable difference of temperature between the fluid particles in contact with one side of the solid plate and those at considerable distances from it.

When heat is to be transferred by convection from one fluid to another, through an intervening layer of metal, the motions of the two fluid masses should, if possible, be in opposite directions, in order that the hottest particles of each fluid may be in communication with the hottest particles of the other, and that the minimum difference of temperature between the adjacent particles of the two fluids may be the greatest possible.

Thus, in the surface condensation of steam, by passing it through metal tubes immersed in a current of cold water or air, the cooling fluid should be made to move in the opposite direction to the condensing steam.

### Steam-pipe Coverings.

It will be observed that several of the incombustible materials are nearly as efficient as wool, cotton, and feathers, with which they may be compared in the preceding table. The materials which may be considered wholly free from the danger of being carbonized or ignited by slow contact with pipes or boilers are printed in Roman type. Those which are more or less liable to be carbonized are printed in italics.

The results Nos. 1 to 20 inclusive were from experiments with the various non-conductors each used in a mass one inch thick, placed on a flat surface of iron kept heated by steam to 310° F. The substances Nos. 21 to

32 were tried as coverings for two-inch steam pipe; the results being reduced to the same terms as the others for convenience of comparison.

Experiments on still air gave results which differ little from those of Nos. 3, 4, and 6. The bulk of matter in the best non-conductors is relatively too small to have any specific effect except to trap the air and keep it stagnant. These substances keep the air still by virtue of the roughness of their fibres or particles. The asbestos, No. 18, had smooth fibres. Asbestos with exceedingly fine fibre made a somewhat better showing, but asbestos is really one of the poorest non-conductors. It may be used advantageously to hold together other incombustible substances, but the less of it the better. A "magnesia" covering, made of carbonate of magnesia with a small percentage of good asbestos fibre and containing 0.25 of solid matter, transmitted 2.5 B. T. U. per square foot per minute, and one containing 0.396 of solid matter transmitted 3.33 B. T. U.

Any suitable substance which is used to prevent the escape of steam heat should not be less than one inch thick.

Any covering should be kept perfectly dry, for not only is water a good carrier of heat, but it has been found that still water conducts heat about eight times as rapidly as still air.

**Tests of Commercial Coverings** were made by Mr. Geo. M. Brill and reported in Trans. A. S. M. E., xvi, 827. A length of 60 feet of 8-inch steam-pipe was used in the tests, and the heat loss was determined by the condensation. The steam pressure was from 109 to 117 lbs. gauge, and the temperature of the air from 58° to 81° F. The difference between the temperature of steam and air ranged from 263° to 286°, averaging 272°.

The following are the principal results :

Kind of Covering.	Thickness of Covering, inches.	Lbs. Steam condensed per sq. ft. per hour.	B. T. U. per sq. ft. per minute.	B. T. U. per sq. ft. per hour per degree of average difference of temperature.	Saving due to covering lbs. steam per hour per sq. ft.	Ratio of Heat lost, Bare to Covered Pipe, %.	H. P. lost per 100 sq. ft. of pipe (30 lbs. per hour = 1 H. P.).

**Transmission of Heat, through Solid Plates, from Water to Water.** (Clark, S.E.).—M. Péçlet found, from experiments made with plates of wrought iron, cast iron, copper, lead, zinc, and tin, that when the fluid in contact with the surface of the plate was not circulated by artificial means, the rate of conduction was the same for different metals and for plates of the same metal of different thicknesses. But when the water was thoroughly circulated over the surfaces, and when these were perfectly clean, the quantity of transmitted heat was inversely proportional to the thickness, and directly as the difference in temperature of the two faces of the plate. When the metal surface became dull, the rate of transmission of heat through all the metals was very nearly the same.

It follows, says Clark, that the absorption of heat through metal plates is more active whilst evaporation is in progress—when the circulation of the water is more active—than while the water is being heated up to the boiling point.

**Transmission from Steam to Water.**—M. Pécelet's principle is supported by the results of experiments made in 1867 by Mr. Isherwood on the conductivity of different metals. Cylindrical pots, 10 inches in diameter, 21¼ inches deep inside, and ¼ inch, ¼ inch, and ¾ inch thick, turned and bored, were formed of pure copper, brass (60 copper and 40 zinc), rolled wrought iron, and remelted cast iron. They were immersed in a steam bath, which was varied from 220° to 320° F. Water at 212° was supplied to the pots, which were kept filled. It was ascertained that the rate of evaporation was in the direct ratio of the difference of the temperatures inside and outside of the pots; that is, that the rate of evaporation per degree of difference of temperatures was the same for all temperatures; and that the rate of evaporation was exactly the same for different thicknesses of the metal. The respective rates of conductivity of the several metals were as follows, expressed in weight of water evaporated from and at 212° F. per square foot of the interior surface of the pots per degree of difference of temperature per hour, together with the equivalent quantities of heat-units:

	Water at 212°,	Heat-units.	Ratio.
Copper.....	.665 lb.	642.5	1.00
Brass.....	.577 "	556.8	.87
Wrought iron.....	.387 "	373.6	.58
Cast iron.....	.327 "	315.7	.49

Whitham, "Steam Engine Design," p. 283, also Trans. A. S. M. E. ix, 425, in using these data in deriving a formula for surface condensers calls these figures those of perfect conductivity, and multiplies them by a coefficient *C*, which he takes at 0.323, to obtain the efficiency of condenser surface in ordinary use, i. e., coated with saline and greasy deposits.

**Transmission of Heat from Steam to Water through Coils of Iron Pipe.**—H. G. C. Kopp and F. J. Meystre (*Stevens Indicator*, Jan., 1894), give an account of some experiments on transmission of heat through coils of pipe. They collate the results of earlier experiments as follows, for comparison:

Experimenter.	Character of Surface.	Steam Condensed per Square foot per degree difference of temperature per hour.		Heat transmitted per square foot per degree difference of temperature per hour.		Remarks.
		Heating, pounds.	Evaporating, pounds.	Heating, B. T. U.	Evaporating, B. T. U.	
Laurens	Copper coils...	.292	.981	315	974	} Steam pressure = 100. } Steam pressure = 10.
"	2 Copper coils.	....	1.20	....	1120

Perkins.	Iron coil.....	....	.24	....	215	
"	" ".....	....	.22	....	208.2	
Box.....	Iron tube.....	.235	....	230	.....	
".....	" ".....	.196	....	207	.....	
".....	" ".....	.206	....	210	.....	
Havrez..	Cast-iron boiler.....	.077	.105	82	100	

From the above it would appear that the efficiency of iron surfaces is less than that of copper coils, plate surfaces being far inferior.

In all experiments made up to the present time, it appears that the temperature of the condensing water was allowed to rise, a mean between the initial and final temperatures being accepted as the effective temperature. But as water becomes warmer it circulates more rapidly, thereby causing the water surrounding the coil to become agitated and replaced by cooler water, which allows more heat to be transmitted.

Again, in accepting the mean temperature as that of the condensing medium, the assumption is made that the rate of condensation is in direct proportion to the temperature of the condensing water.

In order to correct and avoid any error arising from these assumptions and approximations, experiments were undertaken, in which all the conditions were constant during each test.

The pressure was maintained uniform throughout the coil, and provision was made for the free outflow of the condensed steam, in order to obtain at all times the full efficiency of the condensing surface. The condensing water was continually stirred to secure uniformity of temperature, which was regulated by means of a steam-pipe and a cold-water pipe entering the tank in which the coil was placed.

The following is a condensed statement of the results

HEAT TRANSMITTED PER SQUARE FOOT OF COOLING SURFACE, PER HOUR, PER DEGREE OF DIFFERENCE OF TEMPERATURE. (British Thermal Units.)

Temperature of Condensing Water.	1-in. Iron Pipe; Steam inside, 60 lbs. Gauge Pressure.	1½ in. Pipe; Steam inside, 10 lbs. Pressure.	1½ in. Pipe; Steam outside, 10 lbs. Pressure.	1½ in. Pipe; Steam inside, 60 lbs. Pressure.
80	265	128	200	....
100	269	130	230	239
120	272	137	260	247
140	277	145	267	276
160	281	158	271	306
180	299	174	270	349
200	313	...	....	419

The results indicate that the heat transmitted per degree of difference of temperature in general increases as the temperature of the condensing water is increased.

The amount transmitted is much larger with the steam on the outside of the coil than with the steam inside the coil. This may be explained in part by the fact that the condensing water when inside the coil flows over the surface of conduction very rapidly, and is more efficient for cooling than when contained in a tank outside of the coil.

This result is in accordance with that found by Mr. Thomas Craddock, which indicated that the rate of cooling by transmission of heat through metallic surfaces was almost wholly dependent on the rate of circulation of the cooling medium over the surface to be cooled.

**Transmission of Heat in Condenser Tubes.** (*Eng'g*, Dec. 10, 1875, p. 449.).—In 1874 B. C. Nichol made experiments for determining the rate at which heat was transmitted through a condenser tube. The results went to show that the amount of heat transmitted through the walls of the tube per estimated degree of mean difference of temperature increased considerably with this difference. For example:

Estimated mean difference of temperature between inside and outside of tube, degrees Fahr.	Vertical Tube.			Horizontal Tube		
	128	151.9	152.9	111.6	146.2	150.4
Heat-units transmitted per hour per square foot of surface per degree of mean diff. of temp....	422	531	561	610	737	823

These results seem to throw doubt upon Mr. Sherwood's statement that the rate of evaporation per degree of difference of temperature is the same for all temperatures.

Mr. Thomas Craddock found that water was enormously more efficient than air for the abstraction of heat through metallic surfaces in the process of cooling. He proved that the rate of cooling by transmission of heat through metallic surfaces depends upon the rate of circulation of the cooling medium over the surface to be cooled. A tube filled with hot water, moved by rapid rotation at the rate of 59 ft. per second, through air, lost as much heat in one minute as it did in still air in 12 minutes. In water, at a velocity of 3 ft. per second, as much heat was abstracted in half a minute as was abstracted in one minute when it was at rest in the water. Mr. Craddock concluded, further, that the circulation of the cooling fluid became of

greater importance as the difference of temperature on the two sides of the plate became less. (Clark, R. T. D., p. 461.)

**Heat Transmission through Cast-iron Plates Pickled in Nitric Acid.**—Experiments by R. C. Carpenter (Trans. A. S. M. E., xii 179) show a marked change in the conducting power of the plates (from steam to water), due to prolonged treatment with dilute nitric acid.

The action of the nitric acid, by dissolving the free iron and not attacking the carbon, forms a protecting surface to the iron, which is largely composed of carbon. The following is a summary of results:

Character of Plates, each plate 8.4 in. by 5.4 in., exposed surface 27 sq. ft.	Increase in Temperature of 3.125 lbs. of Water each Minute.	Proportionate Thermal Units Transmitted for each Degree of Difference of Temperature per Square Foot per Hour.	Relative Transmission of Heat.

“ “ 5% sol., 40 days.	10.6	77.4	68.5
Plate of pine wood, same dimensions as the plate of cast iron.....	0.33	1.9	1.6

The effect of covering cast-iron surfaces with varnish has been investigated by P. M. Chamberlain. He subjected the plate to the action of strong acid for a few hours, and then applied a non conducting varnish. One surface only was treated. Some of his results are as follows:

Heat units per sq. ft. per hour, for each degree, $\tau - \tau'$ .	}	170. As finished—greasy.
		152. “ “ washed with benzine and dried.
		169. Oiled with lubricating oil.
		162. After exposure to nitric acid sixteen hours, then oiled (linseed oil.)
		166. After exposure to hydrochloric acid twelve hours, then oiled (linseed oil.)
		113. { After exposure to sulphuric acid 1, water 2, for 48 hours,
		117. } then oiled, varnished, and allowed to dry for 24 hours.

**Transmission of Heat through Solid Plates from Air or other Dry Gases to Water.** (From Clark on the Steam Engine.)

—The law of the transmission of heat from hot air or other gases to water, through metallic plates, has not been exactly determined by experiment. The general results of experiments on the evaporative action of different portions of the heating surface of a steam-boiler point to the general law that the quantity of heat transmitted per degree difference of temperature is practically uniform for various differences of temperature.

The communication of heat from the gas to the plate surface is much accelerated by mechanical impingement of the gaseous products upon the surface.

Clark says that when the surfaces are perfectly clean, the rate of transmission of heat through plates of metal from air or gas to water is greater for copper, next for brass, and next for wrought iron. But when the surfaces are dimmed or coated, the rate is the same for the different metals.

With respect to the influence of the conductivity of metals and of the thickness of the plate on the transmission of heat from burnt gases to water, Mr. Napier made experiments with small boilers of iron and copper placed over a gas-flame. The vessels were 5 inches in diameter and  $2\frac{1}{2}$  inches deep. From three vessels, one of iron, one of copper, and one of iron sides and copper bottom, each of them  $\frac{1}{30}$  inch in thickness, equal quantities of water were evaporated to dryness, in the times as follows :

Water.	Iron Vessel.	Copper Vessel.	Iron and Copper Vessel.
4 ounces	19 minutes	18.5 minutes	.....
11 “	33 “	30.75 “	.....
5½ “	50 “	44 “	.....
4 “	35.7 “	.....	36.83 minutes.

Two other vessels of iron sides 1/30 inch thick, one having a ¼-inch copper bottom and the other a ¼-inch lead bottom, were tested against the iron and copper vessel, 1/30 inch thick. Equal quantities of water were evaporated in 54, 55, and 53½ minutes respectively. Taken generally, the results of these experiments show that there are practically but slight differences between iron, copper, and lead in evaporative activity, and that the activity is not affected by the thickness of the bottom.

Mr. W. B. Johnson formed a like conclusion from the results of his observations of two boilers of 160 horse-power each, made exactly alike, except that one had iron flue-tubes and the other copper flue-tubes. No difference could be detected between the performances of these boilers.

Divergencies between the results of different experimenters are attributable probably to the difference of conditions under which the heat was transmitted, as between water or steam and water, and between gaseous matter and water. On one point the divergence is extreme: the rate of transmission of heat per degree of difference of temperature. Whilst from 400 to 600 units of heat are transmitted from water to water through iron plates, per degree of difference per square foot per hour, the quantity of heat transmitted between water and air, or other dry gas, is only about from 2 to 5 units, according as the surrounding air is at rest or in movement. In a locomotive boiler, where radiant heat was brought into play, 17 units of heat were transmitted through the plates of the fire-box per degree of difference of temperature per square foot per hour.

**Transmission of Heat through Plates and Tubes from Steam or Hot Water to Air.**—The transfer of heat from steam or water through a plate or tube into the surrounding air is a complex operation, in which the internal and external conductivity of the metal, the radiating power of the surface, and the convection of heat in the surrounding air are all concerned. Since the quantity of heat radiated from a surface varies with the condition of the surface and with the surroundings, according to laws not yet determined, and since the heat carried away by convection varies with the rate of the flow of the air over the surface, it is evident that no general law can be laid down for the total quantity of heat emitted.

The following is condensed from an article on Loss of Heat from Steam-pipes, in *The Locomotive*, Sept. and Oct., 1892.

A hot steam-pipe is radiating heat constantly off into space, but at the same time it is cooling also by convection. Experimental data on which to base calculations of the heat radiated and otherwise lost by steam-pipes are neither numerous nor satisfactory.

In Box's Practical Treatise on Heat a number of results are given for the amount of heat radiated by different substances when the temperature of the air is 1° Fahr. lower than the temperature of the radiating body. A portion of this table is given below. It is said to be based on Péclet's experiments.

HEAT UNITS RADIATED PER HOUR, PER SQUARE FOOT OF SURFACE, FOR 1° FAHRENHEIT EXCESS IN TEMPERATURE.

Copper, polished .....	.0327	Sheet-iron, ordinary.....	.5662
Tin, polished .....	.0440	Glass.....	.5948
Zinc and brass, polished.....	.0491	Cast iron, new.....	.6480
Tinned iron, polished.....	.0858	Common steam-pipe, inferred..	.6400
Sheet-iron, polished .....	.0920	Cast and sheet iron, rusted ....	.6868
Sheet lead .....	.1329	Wood, building stone, and brick	.7358

When the temperature of the air is about 50° or 60° Fahr., and the radiating body is not more than about 30° hotter than the air, we may calculate the radiation of a given surface by assuming the amount of heat given off by it in a given time to be proportional to the difference in temperature between the radiating body and the air. This is "Newton's law of cooling." But when the difference in temperature is great, Newton's law does not hold good; the radiation is no longer proportional to the difference in temperature, but must be calculated by a complex formula established experimentally by Dulong and Petit. Box has computed a table from this formula, which greatly facilitates its application, and which is given below :

## FACTORS FOR REDUCTION TO DULONG'S LAW OF RADIATION.

Differences in Temperature between Radiating Body and the Air.	Temperature of the Air on the Fahrenheit Scale.

The loss of heat by *convection* appears to be independent of the nature of the surface, that is, it is the same for iron, stone, wood, and other materials. It is different for bodies of different shape, however, and it varies with the position of the body. Thus a vertical steam-pipe will not lose so much heat by convection as a horizontal one will; for the air heated at the lower part of the vertical pipe will rise along the surface of the pipe, protecting it to some extent from the chilling action of the surrounding cooler air. For a similar reason the shape of a body has an important influence on the result, those bodies losing most heat whose forms are such as to allow the cool air free access to every part of their surface. The following table from Box gives the number of heat units that horizontal cylinders or pipes lose by convection per square foot of surface per hour, for one degree difference in temperature between the pipe and the air.

HEAT UNITS LOST BY CONVECTION FROM HORIZONTAL PIPES, PER SQUARE FOOT OF SURFACE PER HOUR, FOR A TEMPERATURE DIFFERENCE OF 1° FAHR.

External Diameter of Pipe in inches.	Heat Units Lost.	External Diameter of Pipe in inches.	Heat Units Lost.	External Diameter of Pipe in inches.	Heat Units Lost.
2	0.728	7	0.509	18	0.455
3	0.626	8	0.498	24	0.447
4	0.574	9	0.489	36	0.433
5	0.544	10	0.482	48	0.434
6	0.523	12	0.472	..	.....

The loss of heat by convection is nearly proportional to the difference in temperature between the hot body and the air; but the experiments of

Dulong and Péclet show that this is not exactly true, and we may here also resort to a table of factors for correcting the results obtained by simple proportion.

FACTORS FOR REDUCTION TO DULONG'S LAW OF CONVECTION.

Difference in Temp. between Hot Body and Air.	Factor.	Difference in Temp. between Hot Body and Air.	Factor.	Difference in Temp. between Hot Body and Air.	Factor.
18° F.	0.94	180° F.	1.62	342° F.	1.87
36°	1.11	198°	1.65	360°	1.90
54°	1.22	216°	1.68	378°	1.92
72°	1.30	234°	1.72	396°	1.94
90°	1.37	252°	1.74	414°	1.96
108°	1.43	270°	1.77	432°	1.98
126°	1.49	288°	1.80	450°	2.00
144°	1.53	306°	1.83	468°	2.02
162°	1.58	324°	1.85	....	....

EXAMPLE IN THE USE OF THE TABLES.—Required the total loss of heat by both radiation and convection, per foot of length of a steam-pipe 2 11/32 in. external diameter, steam pressure 60 lbs., temperature of the air in the room 68° Fahr.

Temperature corresponding to 60 lbs. equals 307°; temperature difference = 307 - 68 = 239°.

Area of one foot length of steam-pipe = 2 11/32 × 3.1416 ÷ 12 = 0.614 sq. ft.

Heat radiated per hour per square foot per degree of difference, from table, 0.64.

Radiation loss per hour by Newton's law = 239° × .614 ft. × .64 = 93.9 heat units. Same reduced to conform with Dulong's law of radiation: factor from table for temperature difference of 239° and temperature of air 68° = 1.93. 93.9 × 1.93 = 181.2 heat units, total loss by radiation.

Convection loss per square foot per hour from a 2 11/32-inch pipe: by interpolation from table, 2'' = .728, 3'' = .626, 2 11/32'' = .693.

Area, .614 × .693 × 239° = 101.7 heat units. Same reduced to conform with Dulong's law of convection: 101.7 × 1.73 (from table) = 175.9 heat units per hour. Total loss by radiation and convection = 181.2 + 175.9 = 357.1 heat units per hour. Loss per degree of difference of temperature per linear foot of pipe per hour = 357.1 ÷ 239 = 1.494 heat units = 2.433 per sq. ft.

It is not claimed, says *The Locomotive*, that the results obtained by this method of calculation are strictly accurate. The experimental data are not sufficient to allow us to compute the heat-loss from steam-pipes with any great degree of refinement; yet it is believed that the results obtained as indicated above will be sufficiently near the truth for most purposes. An experiment by Prof. Ordway, in a pipe 2 11/32 in. diam. under the above conditions (Trans. A. S. M. E., v. 73), showed a condensation of steam of 181 grammes per hour, which is equivalent to a loss of heat of 358.7 heat units per hour, or within half of one per cent of that given by the above calculation.

According to different authorities, the quantity of heat given off by steam and hot-water radiators in ordinary practice of heating of buildings by direct radiation varies from 1.8 to about 3 heat units per hour per square foot per degree of difference of temperature.

The lowest figure is calculated from the following statement by Robert Briggs in his paper on "American Practice in Warming Buildings by Steam" (Proc. Inst. C. E., 1882, vol. lxxi): "Each 100 sq. ft. of radiating surface will give off 3 Fahr. heat units per minute for each degree F. of difference in temperature between the radiating surface and the air in which it is exposed."

The figure 2 1/2 heat units is given by the Nason Manufacturing Company in their catalogue, and 2 to 2 1/4 are given by many recent writers.

For the ordinary temperature difference in low-pressure steam-heating, say 212° - 70° = 142° F., 1 lb. steam condensed from 212° to water at the

same temperature gives up 965.7 heat units. A loss of 2 heat units per sq. ft. per hour per degree of difference, under these conditions, is equivalent to  $2 \times 142 \div 965 = 0.3$  lbs. of steam condensed per hour per sq. ft. of heating surface. (See also Heating and Ventilation.)

**Transmission of Heat through Walls, etc., of Buildings** (Nason Manufacturing Co.). (See also Heating and Ventilation.)—Heat has the remarkable property of passing through moderate thicknesses of air and gases without appreciable loss, so that air is not warmed by radiant heat, but by contact with surfaces that have absorbed the radiation.

POWERS OF DIFFERENT SUBSTANCES FOR TRANSMITTING HEAT.

Window-glass .....	1000	Bricks, rough.....	200 to 250
Oak or walnut.....	66	Bricks, whitewashed....	200
White pine .....	80	Granite or slate.. .....	250
Pitch-pine.....	100	Sheet iron.....	1030 to 1110
Lath or plaster .....	75 to 100		

A square foot of glass will cool 1.279 cubic feet of air from the temperature inside to that outside per minute, and outside wall surface is generally estimated at one fifth of the rate of glass in cooling effect.

Box, in his "Practical Treatise on Heat," gives a table of the conducting powers of materials prepared from the experiments of Péclet. It gives the quantity of heat in units transmitted per square foot per hour by a plate 1 inch in thickness, the two surfaces differing in temperature 1 degree:

Fine-grained gray marble.....	28.00
Coarse-grained white marble.....	22.4
Stone, calcareous, fine.....	16.7
Stone, calcareous, ordinary.....	13.68
Baked clay, brickwork .....	4.83
Brick-dust, sifted.....	1.33

Hood, in his "Warming and Ventilating of Buildings," p. 249, gives the results of M. Depretz, which, placing the conducting power of marble at 1.00, give .483 as the value for firebrick.

**THERMODYNAMICS.**

**Thermodynamics**, the science of heat considered as a form of energy, is useful in advanced studies of the theory of steam, gas, and air engines, refrigerating machines, compressed air, etc. The method of treatment adopted by the standard writers is severely mathematical, involving constant application of the calculus. The student will find the subject thoroughly treated in the recent works by Rontgen (Dubois's translation), Wood, and Peabody.

**First Law of Thermodynamics.**—Heat and mechanical energy are mutually convertible in the ratio of about 778 foot-pounds for the British thermal unit. (Wood.) Heat is the living force or *vis viva* due to certain molecular motions of the molecules of bodies, and this living force may be stated or measured in units of heat or in foot-pounds, a unit of heat in British measures being equivalent to 772 [778] foot-pounds. (Trowbridge, Trans. A. S. M. E., vii. 727.)

**Second Law of Thermodynamics.**—The second law has by different writers been stated in a variety of ways, and apparently with ideas so diverse as not to cover a common principle. (Wood, Therm., p. 389.)

It is impossible for a self-acting machine, unaided by any external agency to convert heat from one body to another at a higher temperature. (Clausius.)

If all the heat absorbed be at one temperature, and that rejected be at one lower temperature, then will the heat which is transmuted into work be to the entire heat absorbed in the same ratio as the difference between the absolute temperature of the source and refrigerator is to the absolute temperature of the source. In other words, the second law is an expression for the efficiency of the perfect elementary engine. (Wood.)

The living force, or *vis viva*, of a body (called heat) is always proportional to the absolute temperature of the body. (Trowbridge.)

The expression  $\frac{Q_1 - Q_2}{Q_1} = \frac{T_1 - T_2}{T_1}$  may be called the symbolical or algebraic enunciation of the second law,—the law which limits the efficiency of heat engines, and which does not depend on the nature of the working medium employed. (Trowbridge.)  $Q_1$  and  $T_1$  = quantity and absolute

temperature of the heat received,  $Q_2$  and  $T_2$  = quantity and absolute temperature of the heat rejected.

The expression  $\frac{T_1 - T_2}{T_1}$  represents the efficiency of a perfect heat engine which receives all its heat at the absolute temperature  $T_1$ , and rejects heat at the temperature  $T_2$ , converting into work the difference between the quantity received and rejected.

**EXAMPLE.**—What is the efficiency of a perfect heat engine which receives heat at  $388^\circ$  F. (the temperature of steam of 200 lbs. gauge pressure) and rejects heat at  $100^\circ$  F. (temperature of a condenser, pressure 1 lb. above vacuum).

$$\frac{388 + 459.2 - (100 + 459.2)}{388 + 459.2} = 34\%, \text{ nearly.}$$

In the actual engine this efficiency can never be attained, for the difference between the quantity of heat received into the cylinder and that rejected into the condenser is not all converted into work, much of it being lost by radiation, leakage, etc. In the steam engine the phenomenon of cylinder condensation also tends to reduce the efficiency.

## PHYSICAL PROPERTIES OF GASES.

(Additional matter on this subject will be found under Heat, Air, Gas, and Steam.)

When a mass of gas is enclosed in a vessel it exerts a pressure against the walls. This pressure is uniform on every square inch of the surface of the vessel; also, at any point in the fluid mass the pressure is the same in every direction.

In small vessels containing gases the increase of pressure due to weight may be neglected, since all gases are very light; but where liquids are concerned, the increase in pressure due to their weight must always be taken into account.

**Expansion of Gases, Marriotte's Law.**—The volume of a gas diminishes in the same ratio as the pressure upon it is increased.

This law is by experiment found to be very nearly true for all gases, and is known as Boyle's or Mariotte's law.

If  $p$  = pressure at a volume  $v$ , and  $p_1$  = pressure at a volume  $v_1$ ,  $p_1 v_1 = pv$ ;  $p_1 = \frac{v}{v_1} p$ ;  $pv = a$  constant.

The constant,  $C$ , varies with the temperature, everything else remaining the same.

Air, compressed by a pressure of seventy-five atmospheres has a volume about 2% less than that computed from Boyle's law, but this is the greatest divergence that is found below 160 atmospheres pressure.

**Law of Charles.**—The volume of a perfect gas at a constant pressure is proportional to its absolute temperature. If  $v_0$  be the volume of a gas at  $32^\circ$  F., and  $v_1$  the volume at any other temperature,  $t_1$ , then

$$v_1 = v_0 \left( \frac{t_1 + 459.2}{491.2} \right); \quad v_1 = \left( 1 + \frac{t_1 - 32^\circ}{491.2} \right) v_0,$$

$$\text{or} \quad v_1 = [1 + 0.002036(t_1 - 32^\circ)] v_0.$$

If the pressure also change from  $p_0$  to  $p_1$ ,

$$v_1 = v_0 \frac{p_0}{p_1} \left( \frac{t_1 + 459.2}{491.2} \right).$$

**The Densities** of the elementary gases are simply proportional to their atomic weights. The density of a compound gas, referred to hydrogen as 1, is one-half its molecular weight; thus the relative density of  $\text{CO}_2$  is  $\frac{1}{2}(12 + 32) = 22$ .

**Avogadro's Law.**—Equal volumes of all gases, under the same conditions of temperature and pressure, contain the same number of molecules.

To find the weight of a gas in pounds per cubic foot at  $32^\circ$  F., multiply half the molecular weight of the gas by .00559. Thus 1 cu. ft. marsh-gas,  $\text{CH}_4$ ,

$$= \frac{1}{2}(12 + 4) \times .00559 = .0447 \text{ lb.}$$

When a certain volume of hydrogen combines with one half its volume of oxygen, there is produced an amount of water vapor which will occupy the same volume as that which was occupied by the hydrogen gas when at the same temperature and pressure.

**Saturation-point of Vapors.**—A vapor that is not near the saturation-point behaves like a gas under changes of temperature and pressure; but if it is sufficiently compressed or cooled, it reaches a point where it begins to condense: it then no longer obeys the same laws as a gas, but its pressure cannot be increased by diminishing the size of the vessel containing it, but remains constant, except when the temperature is changed. The only gas that can prevent a liquid evaporating seems to be its own vapor.

**Dalton's Law of Gaseous Pressures.**—Every portion of a mass of gas inclosed in a vessel contributes to the pressure against the sides of the vessel the same amount that it would have exerted by itself had no other gas been present.

**Mixtures of Vapors and Gases.**—The pressure exerted against the interior of a vessel by a given quantity of a perfect gas enclosed in it is the sum of the pressures which any number of parts into which such quantity might be divided would exert separately, if each were enclosed in a vessel of the same bulk alone, at the same temperature. Although this law is not exactly true for any actual gas, it is very nearly true for many. Thus if 0.080728 lb. of air at 32° F., being enclosed in a vessel of one cubic foot capacity, exerts a pressure of one atmosphere or 14.7 pounds, on each square inch of the interior of the vessel, then will each additional 0.080728 lb. of air which is enclosed, at 32°, in the same vessel, produce very nearly an additional atmosphere of pressure. The same law is applicable to mixtures of gases of different kinds. For example, 0.12344 lb. of carbonic-acid gas, at 32°, being enclosed in a vessel of one cubic foot in capacity, exerts a pressure of one atmosphere; consequently, if 0.080728 lb. of air and 0.12344 lb. of carbonic acid, mixed, be enclosed at the temperature of 32°, in a vessel of one cubic foot of capacity, the mixture will exert a pressure of two atmospheres. As a second example: Let 0.080728 lb. of air, at 212°, be enclosed in a vessel of one cubic foot; it will exert a pressure of

$$\frac{212 + 459.2}{32 + 459.2} = 1.366 \text{ atmospheres.}$$

Let 0.03797 lb. of steam, at 212°, be enclosed in a vessel of one cubic foot; it will exert a pressure of one atmosphere. Consequently, if 0.080728 lb. of air and 0.03797 lb. of steam be mixed and enclosed together, at 212°, in a vessel of one cubic foot, the mixture will exert a pressure of 2.366 atmospheres. It is a common but erroneous practice, in elementary books on physics, to describe this law as constituting a difference between mixed and homogeneous gases; whereas it is obvious that for mixed and homogeneous gases the law of pressure is exactly the same, viz., that the pressure of the whole of a gaseous mass is the sum of the pressures of all its parts. This is one of the laws of mixture of gases and vapors.

A second law is that the presence of a foreign gaseous substance in contact with the surface of a solid or liquid does not affect the density of the vapor of that solid or liquid unless there is a tendency to chemical combination between the two substances, in which case the density of the vapor is slightly increased. (Rankine, S. E., p. 239.)

**Flow of Gases.**—By the principle of the conservation of energy, it may be shown that the velocity with which a gas under pressure will escape into a vacuum is inversely proportional to the square root of its density; that is, oxygen, which is sixteen times as heavy as hydrogen, would, under exactly the same circumstances, escape through an opening only one fourth as fast as the latter gas.

**Absorption of Gases by Liquids.**—Many gases are readily absorbed by water. Other liquids also possess this power in a greater or less degree. Water will for example, absorb its own volume of carbonic-acid gas, 430 times its volume of ammonia,  $2\frac{1}{3}$  times its volume of chlorine, and only about  $1/20$  of its volume of oxygen.

The weight of gas that is absorbed by a given volume of liquid is proportional to the pressure. But as the volume of a mass of gas is less as the pressure is greater, the volume which a given amount of liquid can absorb at a certain temperature will be constant, whatever the pressure. Water, for example, can absorb its own volume of carbonic-acid gas at atmospheric pressure; it will also dissolve its own volume if the pressure is twice as great, but in that case the gas will be twice as dense; and consequently twice the weight of gas is dissolved.

**AIR.**

**Properties of Air.**—Air is a mechanical mixture of the gases oxygen and nitrogen; 20.7 parts O and 79.3 parts N by volume, 23 parts O and 77 parts N by weight.

The weight of pure air at 32° F. and a barometric pressure of 29.92 inches of mercury, or 14.6963 lbs. per sq. in., or 2116.3 lbs. per sq. ft., is .080728 lb. per cubic foot. Volume of 1 lb. = 12.387 cu. ft. At any other temperature and barometric pressure its weight in lbs. per cubic foot is  $W = \frac{1.3253 \times B}{459.2 + T}$ , where  $B$  = height of the barometer,  $T$  = temperature Fahr., and 1.3253 = weight in lbs. of 459.2 c. ft. of air at 0° F. and one inch barometric pressure. Air expands  $\frac{1}{491.2}$  of its volume at 32° F. for every increase of 1° F., and its volume varies inversely as the pressure.

**Volume, Density, and Pressure of Air at Various Temperatures.** (D. K. Clark.)

Fahr.	Volume at Atmos. Pressure.		Density, lbs. per Cubic Foot at Atmos. Pressure.	Pressure at Constant Volume.

**The Air-manometer** consists of a long vertical glass tube, closed at the upper end, open at the lower end, containing air, provided with a scale, and immersed, along with a thermometer, in a transparent liquid, such as water or oil, contained in a strong cylinder of glass, which communicates with the vessel in which the pressure is to be ascertained. The scale shows the volume occupied by the air in the tube.

Let  $v_0$  be that volume, at the temperature of 32° Fahrenheit, and mean pressure of the atmosphere,  $p_0$ ; let  $v_1$  be the volume of the air at the temperature  $t$ , and under the absolute pressure to be measured  $p_1$ ; then

$$p_1 = \frac{(t + 459.2^\circ)p_0v_0}{491.2^\circ v_1}$$

**Pressure of the Atmosphere at Different Altitudes.**

At the sea-level the pressure of the air is 14.7 pounds per square inch; at  $\frac{1}{4}$  of a mile above the sea-level it is 14.02 pounds; at  $\frac{1}{2}$  mile, 13.33; at  $\frac{3}{4}$  mile, 12.66; at 1 mile, 12.02; at  $1\frac{1}{4}$  mile, 11.42; at  $1\frac{1}{2}$  mile, 10.88; and at  $2$

miles, 9.80 pounds per square inch. For a rough approximation we may assume that the pressure decreases  $\frac{1}{2}$  pound per square inch for every 1000 feet of ascent.

It is calculated that at a height of about  $3\frac{1}{2}$  miles above the sea-level the weight of a cubic foot of air is only one half what it is at the surface of the earth, at seven miles only one fourth, at fourteen miles only one sixteenth, at twenty-one miles only one sixty-fourth, and at a height of over forty-five miles it becomes so attenuated as to have no appreciable weight.

The pressure of the atmosphere increases with the depth of shafts, equal to about one inch rise in the barometer for each 900 feet increase in depth: this may be taken as a rough-and-ready rule for ascertaining the depth of shafts.

### Pressure of the Atmosphere per Square Inch and per Square Foot at Various Readings of the Barometer.

RULE.—Barometer in inches  $\times .4908$  = pressure per square inch; pressure per square inch  $\times 144$  = pressure per square foot.

Barometer.	Pressure per Sq. In.	Pressure per Sq. Ft.	Barometer.	Pressure per Sq. In.	Pressure per Sq. Ft.
in.	lbs.	lbs.*	in.	lbs.	lbs.*
28.00	13.74	1978	29.75	14.60	2102
28.25	13.86	1995	30.00	14.72	2119

### Levelling by the Barometer and by Boiling Water.

(Trautwine.)—Many circumstances combine to render the results of this kind of levelling unreliable where great accuracy is required. It is difficult to read off from an aneroid (the kind of barometer usually employed for engineering purposes) to within from two to five or six feet, depending on its size. The moisture or dryness of the air affects the results; also winds, the vicinity of mountains, and the daily atmospheric tides, which cause incessant and irregular fluctuations in the barometer. A barometer hanging quietly in a room will often vary  $\frac{1}{4}$  of an inch within a few hours, corresponding to a difference of elevation of nearly 100 feet. No formula can possibly be devised that shall embrace these sources of error.

**To Find the Difference in Altitude of Two Places.**—Take from the table the altitudes opposite to the two boiling temperatures, or to the two barometer readings. Subtract the one opposite the lower reading from that opposite the upper reading. The remainder will be the required height, as a rough approximation. To correct this, add together the two thermometer readings, and divide the sum by 2, for their mean. From table of corrections for temperature, take out the number under this mean. Multiply the approximate height just found by this number.

At 70° F. pure water will boil at 1° less of temperature for an average of about 550 feet of elevation above sea-level, up to a height of 1/2 a mile. At the height of 1 mile, 1° of boiling temperature will correspond to about 560 feet of elevation. In the table the mean of the temperatures at the two stations is assumed to be 32° F., at which no correction for temperature is necessary in using the table.

Boiling-point in deg. Fah.	Barom. in.	Altitude above Sea-level, feet.	Boiling-point in deg. Fah.	Barom. in.	Altitude above Sea-level, feet.	Boiling-point in deg. Fah.	Barom. in.	Altitude above Sea-level, feet.

**Moisture in the Atmosphere.**—Atmospheric air always contains a small quantity of carbonic acid (see Ventilation, p. 528) and a varying quantity of aqueous vapor or moisture. The relative humidity of the air at any time is the percentage of moisture contained in it as compared with the amount it is capable of holding at the same temperature.

The degree of saturation or relative humidity of the air is determined by the use of the dry and wet bulb thermometer. The degree of saturation for a number of different readings of the thermometer is given in the following table, condensed from the Hygrometric Tables of the U. S. Weather Bureau:

RELATIVE HUMIDITY, PER CENT.

The weight in lbs. of the vapor mixed with 100 lbs. of pure air at any given temperature and pressure is given by the formula

$$\frac{62.3 \times E}{29.92 - E} \times \frac{29.92}{p},$$

where  $E$  = elastic force of the vapor at the given temperature, in inches of mercury;  $p$  = absolute pressure in inches of mercury, = 29.92 for ordinary atmospheric pressure.

**Specific Heat of Air at Constant Volume and at Constant Pressure.**—Volume of 1 lb. of air at 32° F. and pressure of 14.7 lbs. per sq. in. = 12.387 cu. ft. = a column 1 sq. ft. area  $\times$  12.387 ft. high. Raising temperature 1° F. expands it  $\frac{1}{491.2}$  or to 12.4122 ft. high—a rise of .02522 foot.

Work done = 2116 lbs. per sq. ft.  $\times$  .02522 = 53.37 foot-pounds, or 53.37  $\div$  778 = .0686 heat units.

The specific heat of air at constant pressure, according to Regnault, is 0.2375; but this includes the work of expansion, or .0686 heat units; hence the specific heat at constant volume = 0.2375 - .0686 = 0.1689.

Ratio of specific heat at constant pressure to specific heat at constant volume = .2375  $\div$  .1689 = 1.406. (See Specific Heat, p. 458.)

**Flow of Air through Orifices.**—The theoretical velocity in feet per second of flow of any fluid, liquid, or gas through an orifice is  $v = \sqrt{2gh} = 8.02 \sqrt{h}$ , in which  $h$  = the "head" or height of the fluid in feet required to produce the pressure of the fluid at the level of the orifice. (For gases the formula holds good only for small differences of pressure on the two sides of the orifice.) The quantity of flow in cubic feet per second

is equal to the product of this velocity by the area of the orifice, in square feet, multiplied by a "coefficient of flow," which takes into account the contraction of the vein or flowing stream, the friction of the orifice, etc.

For air flowing through an orifice or short tube, from a reservoir of the pressure  $p_1$  into a reservoir of the pressure  $p_2$ , Weisbach gives the following values for the coefficient of flow, obtained from his experiments.

FLOW OF AIR THROUGH AN ORIFICE.

FLIEGNER'S EQUATION FOR FLOW OF AIR FROM A RESERVOIR THROUGH AN ORIFICE. (Proc. Inst. C. E., iv, 379.)

$$G = (3465 - 10000D)F \sqrt{\frac{p_1^2 - p_0^2}{T}}$$

$G$  = the flow in kilogrammes per second;  $p_1 p_0$  = the internal and external pressures in atmospheres of 10,000 kg. per sq. metre;  $D$  = diameter of the orifice in metres;  $F$  = its cross-section in sq. metres;  $T$  = absolute temperature, Centigrade, of the air in the reservoir. The experiments were made with six orifices from 3.17 to 11.36 mm. diameter, in brass plates 12 mm. thick, drilled cylindrically for about  $\frac{1}{2}$  mm., and conically enlarged towards the outside at an angle of  $45^\circ$ .

Clark (Rules, Tables, and Data, p. 891) gives, for the velocity of flow of air through an orifice due to small differences of pressure,

$$V = C \sqrt{\frac{2gh}{12} \times 773.2 \times \left(1 + \frac{t - 32}{493}\right) \times \frac{29.92}{p}}$$

or, simplified,

$$V = 352 C \sqrt{\left(1 + .00203(t - 32)\right) \frac{h}{p}}$$

In which  $V$  = velocity in feet per second;  $2g = 64.4$ ;  $h$  = height of the column of water in inches, measuring the difference of pressure;  $t$  = the temperature Fahr.; and  $p$  = barometric pressure in inches of mercury. 773.2 is the volume of air at  $32^\circ$  under a pressure of 29.92 inches of mercury when that of an equal weight of water is taken as 1.

For  $62^\circ$  F., the formula becomes  $V = 363C \sqrt{\frac{h}{p}}$ , and if  $p = 29.92$  inches  $V =$

$$66.35C \sqrt{h}$$

The coefficient of efflux  $C$ , according to Weisbach, is:

For conoidal mouthpiece, of form of the contracted vein,	
with pressures of from .23 to 1.1 atmospheres.....	$C = .97$ to $.99$
Circular orifices in thin plates.....	$C = .56$ to $.79$
Short cylindrical mouthpieces.....	$C = .81$ to $.84$
The same rounded at the inner end.....	$C = .92$ to $.93$
Conical converging mouthpieces.....	$C = .90$ to $.99$

**Flow of Air in Pipes.**—Hawksley (Proc. Inst. C. E., xxxiii, 55)

states that his formula for flow of water in pipes  $v = 48 \sqrt{\frac{HD}{L}}$  may also

be employed for flow of air. In this case  $H$  = height in feet of a column of air required to produce the pressure causing the flow, or the loss of head

for a given flow;  $v$  = velocity in feet per second,  $D$  = diameter in feet,  $L$  = length in feet.

If the head is expressed in inches of water,  $h$ , the air being taken at 62° F., its weight per cubic foot at atmospheric pressure = .0761 lb. Then  $H = \frac{62.36}{.0761 \times 12} = 68.3h$ . If  $d$  = diameter in inches,  $D = \frac{d}{12}$ , and the formula

becomes  $v = 114.5 \sqrt{\frac{hd}{L}}$ , in which  $h$  = inches of water column,  $d$  = diam-

eter in inches and  $L$  = length in feet;  $h = \frac{Lv^2}{13110d}$ ;  $d = \frac{Lv^2}{13110h}$ .

The quantity in cubic feet per second is

$$Q = .7854 \frac{d^2}{144} v = .6245 \sqrt{\frac{hd^5}{L}}; \quad d = \sqrt[5]{\frac{Q^2 L}{.39h}}; \quad h = \frac{Q^2 L}{.39d^5}.$$

The horse-power required to drive air through a pipe is the volume  $Q$  in cubic feet per second multiplied by the pressure in pounds per square foot and divided by 550. Pressure in pounds per square foot =  $P$  = inches of water column  $\times 5.196$ , whence horse-power =

$$HP. = \frac{QP}{550} = \frac{Qh}{105.9} = \frac{Q^3 L}{41.3d^5}.$$

If the head or pressure causing the flow is expressed in pounds per square inch =  $p$ , then  $h = 27.71p$ , and the above formulæ become

$$v = 602.7 \sqrt{\frac{pd}{L}}; \quad p = \frac{Lv^2}{363,300d}; \quad d = \frac{Lv^2}{363,300p};$$

$$Q = 3.287 \sqrt{\frac{pd^5}{L}}; \quad p = \frac{Q^2 L}{10.806d^5}; \quad d = \sqrt[5]{\frac{Q^2 L}{10.806p}};$$

$$HP. = \frac{Q144p}{550} = .2618Qp = .02421 \frac{Q^3 L}{d^5}.$$

**Volume of Air Transmitted in Cubic Feet per Minute in Pipes of Various Diameters.**

$$\text{Formula } Q = \frac{.7854}{144} d^2 v \times 60.$$

In Hawksley's formula and its derivatives the numerical coefficients are constant. It is scarcely possible, however, that they can be accurate except within a limited range of conditions. In the case of water it is found that the coefficient of friction, on which the loss of head depends, varies with the length and diameter of the pipe, and with the velocity, as well as with the condition of the interior surface. In the case of air and other gases we have, in addition, the decrease in density and consequent increase in volume and in velocity due to the progressive loss of head from one end of the pipe to the other.

Clark states that according to the experiments of D'Aubuisson and those of a Sardinian commission on the resistance of air through long conduits or pipes, the diminution of pressure is very nearly directly as the length, and as the square of the velocity and inversely as the diameter. The resistance is not varied by the density.

If these statements are correct, then the formulæ  $h = \frac{Lv^2}{cd}$  and  $h = \frac{Q^2L}{c'd^5}$  and their derivatives are correct in form, and they may be used when the numerical coefficients  $c$  and  $c'$  are obtained by experiment.

If we take the forms of the above formulæ as correct, and let  $C$  be a variable coefficient, depending upon the length, diameter, and condition of surface of the pipe, and possibly also upon the velocity, the temperature and the density, to be determined by future experiments, then for  $h =$  head in inches,  $d =$  diameter in inches,  $L =$  length in feet,  $v =$  velocity in feet per second, and  $Q =$  quantity in cubic feet per second:

$$v = C\sqrt{\frac{hd}{L}}; \quad d = \frac{Lv^2}{C^2h}; \quad h = \frac{Lv^2}{C^2d};$$

$$Q = .005454C\sqrt{\frac{hd^5}{L}}; \quad d = \sqrt[5]{\frac{33683Q^2L}{C^2h}}; \quad h = \frac{33683Q^2L}{C^2d^5}.$$

For difference or loss of pressure  $p$  in pounds per square inch,

$$h = 27.71p \quad \sqrt{h} = 5.264\sqrt{p};$$

$$v = 5.264C\sqrt{\frac{pd}{L}}; \quad d = \frac{Lv^2}{27.71C^2p}; \quad p = \frac{Lv^2}{27.71C^2d};$$

$$Q = .02871C\sqrt{\frac{pd^5}{L}}; \quad d = \sqrt[5]{\frac{1213Q^2L}{C^2p}}; \quad p = \frac{1213Q^2L}{C^2d^5}.$$

(For other formulæ for flow of air, see Mine Ventilation.)

**Loss of Pressure in Ounces per Square Inch.**—B. F. Sturtevant Company uses the following formulæ :

$$p_1 = \frac{Lv^2}{25000d}; \quad v = \sqrt{\frac{25000dp_1}{L}}; \quad d = \frac{Lv^2}{25000p_1};$$

in which  $p_1 =$  loss of pressure in ounces per square inch,  $v =$  velocity of air in feet per second, and  $L =$  length of pipe in feet. If  $p$  is taken in pounds per square inch, these formulæ reduce to

$$p = .0000025\frac{Lv^2}{d}; \quad v = 632.5\sqrt{\frac{dp_1}{L}}; \quad d = \frac{.0000025Lv^2}{p}.$$

These are deduced from the common formula (Weisbach's),  $p = f\frac{l}{d}\frac{v^3}{2g}$ , in which  $f = .0001608$ .

The following table is condensed from one given in the catalogue of B. F. Sturtevant Company.

Loss of pressure in pipes 100 feet long, in ounces per square inch. For any other length, the loss is proportional to the length.

Velocity of Air, feet per min.	Diameter of Pipe in Inches.											
	1	2	3	4	5	6	7	8	9	10	11	12
	Loss of Pressure in Ounces.

**Compressed-air Transmission.** (Frank Richards, *Am. Mach.*, March 8, 1894)—The volume of free air transmitted may be assumed to be directly as the number of atmospheres to which the air is compressed. Thus, if the air transmitted be at 75 pounds gauge-pressure, or six atmospheres, the volume of free air will be six times the amount given in the table (page 486). It is generally considered that for economical transmission the velocity in main pipes should not exceed 20 feet per second. In the smaller distributing pipes the velocity should be decidedly less than this.

The loss of power in the transmission of compressed air in general is not a serious one, or at all to be compared with the losses of power in the operation of compression and in the re-expansion or final application of the air.

The formulas for loss by friction are all unsatisfactory. The statements of observed facts in this line are in a more or less chaotic state, and self-evidently unreliable.

A statement of the friction of air flowing through a pipe involves at least all the following factors: Unit of time, volume of air, pressure of air, diameter of pipe, length of pipe, and the difference of pressure at the ends of the pipe or the head required to maintain the flow. Neither of these factors can be allowed its independent and absolute value, but is subject to modifications in deference to its associates. The flow of air being assumed to be uniform at the entrance to the pipe, the volume and flow are not uniform after that. The air is constantly losing some of its pressure and its volume is constantly increasing. The velocity of flow is therefore also somewhat accelerated continually. This also modifies the use of the length of the pipe as a constant factor.

Then, besides the fluctuating values of these factors, there is the condition of the pipe itself. The actual diameter of the pipe, especially in the smaller sizes, is different from the nominal diameter. The pipe may be straight, or it may be crooked and have numerous elbows. Mr. Richards considers one elbow as equivalent to a length of pipe.

**Formulae for Flow of Compressed Air in Pipes.**—The formulae on pages 486 and 487 are for air at or near atmospheric pressure. For compressed air the density has to be taken into account. A common formula for the flow of air, gas, or steam in pipes is

$$Q = c \sqrt{\frac{pd^5}{wL}}$$

in which  $Q$  = volume in cubic feet per minute,  $p$  = difference of pressure in lbs. per sq. in. causing the flow,  $d$  = diameter of pipe in in.,  $L$  = length of pipe in ft.,  $w$  = density of the entering gas or steam in lbs. per cu. ft., and  $c$  = a coefficient found by experiment. Mr. F. A. Halsey in calculating a table for the Rand Drill Co.'s Catalogue takes the value of  $c$  at 58, basing it upon the experiments made by order of the Italian government preliminary to boring the Mt. Cenis tunnel. These experiments were made with pipes of 3281 feet in length and of approximately 4, 8, and 14 in. diameter. The volumes of compressed air passed ranged between 16.64 and 1200 cu. ft. per minute. The value of  $c$  is quite constant throughout the range and shows little disposition to change with the varying diameter of the pipe. It is of course probable, says Mr. Halsey, that  $c$  would be smaller if determined for smaller sizes of pipe, but to offset that the actual sizes of small commercial pipe are considerably larger than the nominal sizes, and as these calculations are commonly made for the nominal diameters it is probable that in those small sizes the loss would really be less than shown by the table. The formula is of course strictly applicable to fluids which do not change their density, but within the change of density admissible in the transmission of air for power purposes it is probable that the errors introduced by this change are less than those due to errors of observation in the present state of knowledge of the subject. Mr. Halsey's table is condensed below.

Diameter of Pipe, in inches.	Cubic feet of free air compressed to a gauge-pressure of 80 lbs. and passing through the pipe each minute.											
	50	100	200	400	800	1000	1500	2000	3000	4000	5000

14	.....	.....	.....	.....	.....	.....	.....	.....	.....	0.10	0.16	

To apply the formula given above to air of different pressures it may be given other forms, as follows:

Let  $Q$  = the volume in cubic feet per minute of the compressed air;  $Q_1$  = the volume before compression, or "free air," both being taken at mean atmospheric temperature of 62° F.;  $w_1$  = weight per cubic foot of  $Q_1$  = 0.0761 lb.;  $r$  = atmospheres, or ratio of absolute pressures, = (gauge-pressure + 14.7) ÷ 14.7;  $w$  = weight per cu. ft. of  $Q$ ;  $p$  = difference of pressure, in lbs. per sq. in., causing the flow;  $d$  = diam. of pipe in in.;  $L$  = length of pipe in ft.;  $c$  = experimental constant. Then

$$Q = c \sqrt{\frac{pd^5}{wL}}; \quad Q_1 = rQ; \quad w = rc_1 = .0761r;$$

$$Q = 3.625c \sqrt{\frac{pd^5}{rL}}; \quad Q_1 = 3.625c \sqrt{\frac{pd^5 r}{L}};$$

$$d = \sqrt[5]{.0761 \frac{LQ^2 r}{c^2 p}} = 0.597 \sqrt[5]{\frac{LQ^2 r}{c^2 p}} = \sqrt[5]{.0761 \frac{LQ_1^2}{c^2 p r}} = 0.597 \sqrt[5]{\frac{LQ_1^2}{c^2 p r}};$$

$$p = .0761 \frac{LQ^2 r}{c^2 d^5} = .0761 \frac{LQ_1^2}{c^2 d^5 r}.$$

The value of *c* according to the Mt. Cenis experiments is about 58 for pipes 4, 8, and 14 in. diameter, 3281 ft. long. In the St. Gothard experiments it ranged from 62.8 to 73.2 (see table below) for pipes 5.91 and 7.87 in. diameter, 1713 and 15,092 ft. long. Values derived from D'Arcy's formula for flow of water in pipes, ranging from 45.3 for 1 in. diameter to 63.2 for 24 in., are given under "Flow of Steam," p. 671. For approximate calculations the value 60 may be used for all pipes of 4 in. diameter and upwards. Using *c* = 60, the above formulæ become

$$Q = 217.5 \sqrt{\frac{pd^5}{rL}}; \quad Q_1 = 217.5 \sqrt{\frac{pd^5 r}{L}};$$

$$[d = 0.1161 \sqrt[5]{\frac{LQ^2 r}{p}} = 0.1161 \sqrt[5]{\frac{LQ_1^2}{p r}};$$

$$p = 0.00002114 \frac{LQ^2 r}{d^5} = 0.00002114 \frac{LQ_1^2}{d^5 r}.$$

**Loss of Pressure in Compressed Air Pipe-main, at St. Gothard Tunnel.**

(E. Stockalper.)

Experiment.	Air Main Diameter.	Volume per second of free air, or equivalent volume at atmospheric pressure and 32° F.	Volume per second of compressed air at mean density.	Mean density of compressed air. (Water = 1.)	Weight of air flowing per second.	Mean velocity in feet per second.	Observed Pressures.				Value of $c$ in formula $Q = c \sqrt{\frac{pd^5}{wL}}$ .
							Pressure at beginning of pipe.	Pressure at end of pipe.	Loss of Pressure.		
No.	in.	cu.ft.	cu.ft.	den.	lbs.	feet.	at.	at.	lbs. per sq.in.	%	
1	7.87	33.056	6.534	.00650	2.669	19.32	5.60	5.24	5.292	6.4	73.2
	5.91		7.063	.00603	2.669	37.14	5.24	5.00	3.528	4.6	63.9
2	7.87	22.002	5.509	.00514	1.776	16.30	4.35	4.13	3.234	5.1	70.7
	5.91		5.863	.00482	1.776	.....	4.13	.....	.....	.....	.....
3	7.87	18.364	5.262	.00449	1.483	15.58	3.84	3.65	2.793	5.0	67.6
	5.91		5.580	.00423	1.483	29.34	3.65	3.54	1.617	3.0	62.8

The length of the pipe 7.87 in diameter was 15,092 ft., and of the smaller pipe 1712.6 ft. The mean temperature of the air in the large pipe was 70° F. and in the small pipe 80° F.

**Equation of Pipes.**—It is frequently desired to know what number of pipes of a given size are equal in carrying capacity to one pipe of a larger size. At the same velocity of flow the volume delivered by two pipes of different sizes is proportional to the squares of their diameters; thus, one 4-inch pipe will deliver the same volume as four 2-inch pipes. With the same head, however, the velocity is less in the smaller pipe, and the volume delivered varies about as the square root of the fifth power (i.e., as the 2.5 power). The following table has been calculated on this basis. The figures opposite the intersection of any two sizes is the number of the smaller-sized pipes required to equal one of the larger. Thus, one 4-inch pipe is equal to 5.7 2-inch pipes.

**Measurement of the Velocity of Air in Pipes by an Anemometer.**—Tests were made by B. Donkin, Jr. (*Inst. Civil Engrs.* 1892), to compare the velocity of air in pipes from 8 in. to 24 in. diam., as shown by an anemometer  $2\frac{3}{4}$  in. diam. with the true velocity as measured by the time of descent of a gas-holder holding 1622 cubic feet. A table of the results with discussion is given in *Eng'g News*, Dec. 22, 1892. In pipes from 8 in. to 20 in. diam. with air velocities of from 140 to 690 feet per minute the anemometer showed errors varying from 14.5% fast to 10% slow. With a 24-inch pipe and a velocity of 73 ft. per minute, the anemometer gave from 44 to 63 feet, or from 13.6 to 39.6% slow. The practical conclusion drawn from these experiments is that anemometers for the measurement of velocities of air in pipes of these diameters should be used with great caution. The percentage of error is not constant, and varies considerably with the diameter of the pipes and the speeds of air. The use of a baffle, consisting of a perforated plate, which tended to equalize the velocity in the centre and at the sides in some cases diminished the error.

The impossibility of measuring the true quantity of air by an anemometer held stationary in one position is shown by the following figures, given by Wm. Daniel (Proc. Inst. M. E., 1875), of the velocities of air found at different points in the cross-sections of two different airways in a mine.

**WIND.**

**Force of the Wind.**—Smeaton in 1759 published a table of the velocity and pressure of wind, as follows:

VELOCITY AND FORCE OF WIND, IN POUNDS PER SQUARE INCH.

Miles per hour.	Feet per second.	Force per sq. ft. pounds.	Common Appellation of the Force of Wind.	Miles per Hour.	Feet per second.	Force per sq. ft. pounds.	Common Appellation of the Force of Wind.
1	1.47	0.005	Hardly perceptible.	18	26.4	1.55	Very brisk.
2	2.93	0.020		20	29.34	1.968	
3	4.4	0.044	Just perceptible.	25	36.67	3.075	High wind.
4	5.87	0.079		30	44.01	4.429	
5	7.33	0.123	Gentle pleasant wind.	35	51.34	6.027	Very high storm.
6	8.8	0.177		40	58.68	7.873	
7	10.25	0.241		45	66.01	9.963	
8	11.75	0.315	Pleasant brisk gale.	50	73.35	12.30	Great Storm.
9	13.2	0.400		55	80.7	14.9	
10	14.67	0.492		60	88.02	17.71	
12	17.6	0.708		66	95.4	20.85	
14	20.5	0.964		70	102.5	24.1	
15	22.00	1.107		75	110.	27.7	
16	23.45	1.25	80	117.36	31.49	Hurricane.	
				100	146.67	49.2	Immense hurricane.

The pressures per square foot in the above table correspond to the formula  $P = 0.005V^2$ , in which  $V$  is the velocity in miles per hour. *Eng'g News*, Feb. 9, 1893, says that the formula was never well established, and has floated chiefly on Smeaton's name and for lack of a better. It was put forward only for surfaces for use in windmill practice. The trend of modern evidence is that it is approximately correct only for such surfaces, and that for large solid bodies it often gives greatly too large results. Observations by others are thus compared with Smeaton's formula:

Old Smeaton formula.....	$P = .005V^2$
As determined by Prof. Martin.....	$P = .004V^2$
“ “ Whipple and Dines.....	$P = .0029V^2$

At 60 miles per hour these formulas give for the pressure per square foot, 18, 14.4 and 10.44 lbs., respectively, the pressure varying by all of them as the square of the velocity. Lieut. Crosby's experiments (*Eng'g*, June 13, 1890), claiming to prove that  $P = fV$  instead of  $P = fV^2$ , are discredited.

A. R. Wolff (*The Windmill as a Prime Mover*, p. 9) gives as the theoretical pressure per sq. ft. of surface,  $P = \frac{dQv}{g}$ , in which  $d$  = density of air in pounds

per cu. ft. =  $\frac{.018743(p + P)}{t}$ ;  $p$  being the barometric pressure per square

foot at any level, and temperature of 32° F.,  $t$  any absolute temperature,  $Q$  = volume of air carried along per square foot in one second,  $v$  = velocity of the wind in feet per sec.,  $g = 32.16$ . Since  $Q = v$  cu. ft. per sec.,  $P = \frac{dv^2}{g}$ .

Multiplying this by a coefficient 0.93 found by experiment, and substituting

the above value of  $d$ , he obtains  $P = \frac{0.017431 \times p}{\frac{t \times 32.16}{v^2} - .018743}$ , and when  $p$

= 2116.5 lbs. per sq. ft. or average atmospheric pressure at the sea-level,

$P = \frac{36.8929}{\frac{t \times 32.16}{v^2} - 0.18743}$ , an expression in which the pressure is shown to vary

with the temperature; and he gives a table showing the relation between velocity and pressure for temperatures from 0° to 100° F., and velocities from 1 to 80 miles per hour. For a temperature of 45° F. the pressures agree with those in Smeaton's table, for 0° F. they are about 10 per cent greater, and for 100° 10 per cent less. Prof. H. Allen Hazen, *Eng'g News*, July 5, 1890, says that experiments with whirling arms, by exposing plates to direct wind, and on locomotives with velocities running up to 40 miles per hour, have invariably shown the resistance to vary with  $V^2$ . In the formula  $P = .005SV^2$ , in which  $P$  = pressure in pounds,  $S$  = surface in square feet,  $V$  = velocity in miles per hour, the doubtful question is that regarding the accuracy of the first two factors in the second member of this equation. The first factor has been variously determined from .003 to .005 [it has been determined as low as .0014.—Ed. *Eng'g News*].

The second factor has been found in some experiments with very short whirling arms and low velocities to vary with the perimeter of the plate, but this entirely disappears with longer arms or straight line motion, and the only question now to be determined is the value of the coefficient. Perhaps some of the best experiments for determining this value were tried in France in 1886 by carrying flat boards on trains. The resulting formula in this case was, for 44.5 miles per hour,  $p = .00535SV^2$ .

Mr. Crosby's whirling experiments were made with an arm 5.5 ft. long. It is certain that most serious effects from centrifugal action would be set up by using such a short arm, and nothing satisfactory can be learned with arms less than 20 or 30 ft. long at velocities above 5 miles per hour.

Prof. Kernot, of Melbourne (*Engineering Record*, Feb. 20, 1894), states that experiments at the Forth Bridge showed that the average pressure on surfaces as large as railway carriages, houses, or bridges never exceeded two thirds of that upon small surfaces of one or two square feet, such as have been used at observatories, and also that an inertia effect, which is frequently overlooked, may cause some forms of anemometer to give false results enormously exceeding the correct indication. Experiments of Mr. O. T. Crosby showed that the pressure varied directly as the velocity, whereas all the early investigators, from the time of Smeaton onwards, made it vary as the square of the velocity. Experiments made by Prof. Kernot at speeds varying from 2 to 15 miles per hour agreed with the earlier authorities, and tended to negative Crosby's results. The pressure upon one side of a cube, or of a block proportioned like an ordinary carriage, was found to be .9 of that upon a thin plate of the same area. The same result was obtained for a square tower. A square pyramid, whose height was three times its base, experienced .8 of the pressure upon a thin plate equal to one of its sides, but if an angle was turned to the wind the pressure was increased by fully 20%. A bridge consisting of two plate-girders connected by a deck at the top was found to experience 9 of the pressure on a thin plate equal in size to one girder, when the distance between the girders was equal to their depth, and this was increased by one fifth when the distance between the girders was

double the depth. A lattice-work in which the area of the openings was 55% of the whole area experienced a pressure of 80% of that upon a plate of the same area. The pressure upon cylinders and cones was proved to be equal to half that upon the diametral planes, and that upon an octagonal prism to be 20% greater than upon the circumscribing cylinder. A sphere was subject to a pressure of .36 of that upon a thin circular plate of equal diameter. A hemispherical cup gave the same result as the sphere; when its concavity was turned to the wind the pressure was 1.15 of that on a flat plate of equal diameter. When a plane surface parallel to the direction of the wind was brought nearly into contact with a cylinder or sphere, the pressure on the latter bodies was augmented by about 20%, owing to the lateral escape of the air being checked. Thus it is possible for the security of a tower or chimney to be impaired by the erection of a building nearly touching it on one side.

**Pressures of Wind Registered in Storms.**—Mr. Frizell has examined the published records of Greenwich Observatory from 1849 to 1869, and reports that the highest pressure of wind he finds recorded is 41 lbs. per sq. ft., and there are numerous instances in which it was between 30 and 40 lbs. per sq. ft. Prof. Henry says that on Mount Washington, N. H., a velocity of 150 miles per hour has been observed, and at New York City 60 miles an hour, and that the highest winds observed in 1870 were of 72 and 63 miles per hour, respectively.

Lieut. Dunwoody, U. S. A., says, in substance, that the New England coast is exposed to storms which produce a pressure of 50 lbs. per sq. ft. *Engineering News*, Aug. 20, 1880.

**WINDMILLS.**

**Power and Efficiency of Windmills.**—Rankine, S. E., p. 215, gives the following: Let  $Q$  = volume of air which acts on the sail, or part of a sail, in cubic feet per second,  $v$  = velocity of the wind in feet per second,  $s$  = sectional area of the cylinder, or annular cylinder of wind, through which the sail, or part of the sail, sweeps in one revolution,  $c$  = a coefficient to be found by experience; then  $Q = cvs$ . Rankine, from experimental data given by Smeaton, and taking  $c$  to include an allowance for friction, gives for a wheel with four sails, proportioned in the best manner,  $c = 0.75$ . Let  $A$  = weather angle of the sail at any distance from the axis, i.e., the angle the portion of the sail considered makes with its plane of revolution. This angle gradually diminishes from the inner end of the sail to the tip;  $u$  = the velocity of the same portion of the sail, and  $E$  = the efficiency. The efficiency is the ratio of the useful work performed to whole energy of the stream of wind acting on the surface  $s$  of the wheel, which energy is  $\frac{Dsv^3}{2g}$ ,  $D$  being the weight of a cubic foot of air. Rankine's formula for efficiency is

$$E = \frac{R u}{\frac{Dsv^3}{2g}} = c \left\{ \frac{u}{v} \sin 2A - \frac{u^2}{v^2} (1 - \cos 2A + f) - f \right\},$$

in which  $c = 0.75$  and  $f$  is a coefficient of friction found from Smeaton's data = 0.016. Rankine gives the following from Smeaton's data:

$A$ = weather-angle.....	= 7°	13°	19°
$V \div v$ = ratio of speed of greatest efficiency, for a given weather-angle, to that of the wind.....	= 2.63	1.86	1.41
$E$ = efficiency.....	= 0.24	0.29	0.31

Rankine gives the following as the best values for the angle of weather at different distances from the axis:

Distance in sixths of total radius...	1	2	3	4	5	6
Weather angle.....	18°	19°	18°	16°	12½°	7°

But Wolff (p. 125) shows that Smeaton did not term these the best angles, but simply says they "answer as well as any," possibly any that were in existence in his time. Wolff says that they "cannot in the nature of things be the most desirable angles." Mathematical considerations, he says, conclusively show that the angle of impulse depends on the relative velocity of each point of the sail and the wind, the angle growing larger as the ratio becomes greater. Smeaton's angles do not fulfil this condition. Wolff devel-

ops a theoretical formula for the best angle of weather, and from it calculates a table for different relative velocities of the blades (at a distance of one seventh of the total length from the centre of the shaft) and the wind, from which the following is condensed:

Ratio of the Speed of Blade at 1/7 of Radius to Velocity of Wind.	Distance from the axis of the wheel in sevenths of radius.						
	1	2	3	4	5	6	7
	Best angles of weather.						
0.10	42° 9'	39° 21'	36° 39'	34° 6'	31° 43'	29° 31'	27° 30'
0.15	40 44	36 39	32 53	29 31	26 34	24 0	21 48
0.20	39 21	34 6	29 31	25 40	22 30	19 54	17 46
0.25	37 59	36 43	26 34	22 30	19 20	16 51	14 52
0.30	36 39	29 31	24 0	19 54	16 51	14 32	12 44
0.35	35 21	27 30	21 48	17 46	14 52	12 44	11 6
0.40	34 6	25 40	19 54	16 0	13 17	11 19	9 50
0.45	32 53	24 0	18 16	14 32	11 59	10 10	8 48
0.50	31 43	22 30	16 51	13 17	10 54	9 13	7 58

The effective power of a windmill, as Smeaton ascertained by experiment, varies as  $s$ , the sectional area of the acting stream of wind; that is, for similar wheels, as the squares of the radii.

The value 0.75, assigned to the multiplier  $c$  in the formula  $Q = cvs$ , is founded on the fact, ascertained by Smeaton, that the effective power of a windmill with sails of the best form, and about  $15\frac{1}{2}$  ft. radius, with a breeze of 13 ft. per second, is about 1 horse-power. In the computations founded on that fact, the mean angle of weather is made =  $13^\circ$ . The efficiency of this wheel, according to the formula and table given, is 0.29, at its best speed, when the tips of the sails move at a velocity of 2.6 times that of the wind.

Merivale (Notes and Formulæ for Mining Students), using Smeaton's coefficient of efficiency, 0.29, gives the following:

$U$  = units of work in foot-lbs. per sec.;

$W$  = weight, in pounds, of the cylinder of wind passing the sails each second, the diameter of the cylinder being equal to the diameter of the sails;

$V$  = velocity of wind in feet per second;

H.P. = effective horse-power;

$$U = \frac{WV^2}{64}; \quad \text{H.P.} = \frac{0.29WV^2}{64 \times 550}.$$

A. R. Wolff, in an article in the *American Engineer*, gives the following (see also his treatise on Windmills):

Let  $c$  = velocity of wind in feet per second;

$n$  = number of revolutions of the windmill per minute;

$b_0, b_1, b_2, b_x$  be the breadth of the sail or blade at distances  $l_0, l_1, l_2, l_3$ , and  $l$ , respectively, from the axis of the shaft;

$l_0$  = distance from axis of shaft to beginning of sail or blade proper;

$l$  = distance from axis of shaft to extremity of sail proper;

$v_0, v_1, v_2, v_3, v_x$  = the velocity of the sail in feet per second at distances  $l_0, l_1, l_2, l$ , respectively, from the axis of the shaft;

$\alpha_0, \alpha_1, \alpha_2, \alpha_3, \alpha_x$  = the angles of impulse for maximum effect at distances  $l_0, l_1, l_2, l_3, l$  respectively from the axis of the shaft;

$\alpha$  = the angle of impulse when the sails or blocks are plane surfaces, so that there is but one angle to be considered;

$N$  = number of sails or blades of windmill;

$K$  = .93.

$d$  = density of wind (weight of a cubic foot of air at average temperature and barometric pressure where mill is erected);

$W$  = weight of wind-wheel in pounds;

$f$  = coefficient of friction of shaft and bearings;

$D$  = diameter of bearing of windmill in feet.

The effective horse-power of a windmill with plane sails will equal

$$\frac{(l - l_0)Kc^2dN}{550g} \times \text{mean of} \left( v_0(\sin a - \frac{v_0}{c} \cos a)b_0 \cos a \right. \\ \left. v_x(\sin a - \frac{v_x}{c} \cos a)b_x \cos a \right) - \frac{fW \times .05236nD}{550}$$

The effective horse-power of a windmill of shape of sail for maximum effect equals

$$\frac{N(l - l_0)Kdc^3}{2200g} \times \text{mean of} \left( \frac{2 \sin^2 a_0 - 1}{\sin^2 a_0} b_0, \frac{2 \sin^2 a_1 - 1}{\sin^2 a_1} b_1 \dots \right. \\ \left. \dots \frac{2 \sin^2 a_x - 1}{\sin^2 a_x} b_x \right) - \frac{fW \times .05236nD}{550}$$

The mean value of quantities in brackets is to be found according to Simpson's rule. Dividing *l* into 7 parts, finding the angles and breadths corresponding to these divisions by substituting them in quantities within brackets will be found satisfactory. Comparison of these formulæ with the only fairly reliable experiments in windmills (Coulomb's) showed a close agreement of results.

Approximate formulæ of simpler form for windmills of present construction can be based upon the above, substituting actual average values for *a*, *c*, *d*, and *e*, but since improvement in the present angles is possible, it is better to give the formulæ in their general and accurate form.

Wolff gives the following table based on the practice of an American manufacturer. Since its preparation, he says, over 1500 windmills have been sold on its guaranty (1885), and in all cases the results obtained did not vary sufficiently from those presented to cause any complaint. The actual results obtained are in close agreement with those obtained by theoretical analysis of the impulse of wind upon windmill blades.

**Capacity of the Windmill.**

These windmills are made in regular sizes, as high as sixty feet diameter of wheel; but the experience with the larger class of mills is too limited to enable the presentation of precise data as to their performance.

If the wind can be relied upon in exceptional localities to average a higher velocity for eight hours a day than that stated in the above table, the performance or horse-power of the mill will be increased, and can be obtained by multiplying the figures in the table by the ratio of the cube of the higher average velocity of wind to the cube of the velocity above recorded

He also gives the following table showing the economy of the windmill. All the items of expense, including both interest and repairs, are reduced to the hour by dividing the costs per annum by 365 × 8 = 2920; the interest,

etc., for the twenty-four hours being charged to the eight hours of actual work. By multiplying the figures in the 5th column by 584, the first cost of the windmill, in dollars, is obtained.

**Economy of the Windmill.**

Lieut. I. N. Lewis (*Eng'g Mag.*, Dec. 1894) gives a table of results of experiments with wooden wheels, from which the following is taken:

Diameter of wheel, Feet.	Velocity of Wind, miles per hour.						
	8	10	12	16	20	25	30
	Actual Useful Horse-power developed.						
12	0	1/8	1/4	1/2	1	1 2/3	2
16	1/8	3/8	3/4	1 1/2	2 1/4	3 1/4	4
20	3/4	1 1/4	2	3	4	5 1/2	7
25	1 1/4	1 3/4	3	4 1/2	6	8	10
30	2	3	4	5 1/2	7	9	12

The wheels were tested by driving a differentially wound dynamo. The "useful horse-power" was measured by a voltmeter and ammeter, allowing 500 watts per horse-power. Details of the experiments, including the means used for obtaining the velocity of the wind, are not given. The results are so far in excess of the capacity claimed by responsible manufacturers that they should not be given credence until established by further experiments.

A recent article on windmills in the *Iron Age* contains the following: According to observations of the United States Signal Service, the average velocity of the wind within the range of its record is 9 miles per hour for the year along the North Atlantic border and Northwestern States, 10 miles on the plains of the West, and 6 miles in the Gulf States.

The horse-powers of windmills of the best construction are proportional to the squares of their diameters and inversely as their velocities; for example, a 10-ft. mill in a 16-mile breeze will develop 0.15 horse-power at 65 revolutions per minute; and with the same breeze

- A 20-ft. mill, 40 revolutions, 1 horse-power.
- A 25-ft. mill, 35 revolutions, 1 3/4 horse-power.
- A 30-ft. mill, 28 revolutions, 3 1/2 horse-power.
- A 40-ft. mill, 22 revolutions, 7 1/2 horse-power.
- A 50-ft. mill, 18 revolutions, 12 horse-power.

The increase in power from increase in velocity of the wind is equal to the square of its proportional velocity; as for example, the 25-ft. mill rated

above for a 16-mile wind will, with a 32-mile wind, have its horse-power increased to  $4 \times 1\frac{3}{4} = 7$  horse-power, a 40-ft. mill in a 32-mile wind will run up to 30 horse-power, and a 50-ft. mill to 48 horse-power, with a small deduction for increased friction of air on the wheel and the machinery.

The modern mill of medium and large size will run and produce work in a 4-mile breeze, becoming very efficient in an 8 to 16-mile breeze, and increase its power with safety to the running-gear up to a gale of 45 miles per hour.

Prof. Thurston, in an article on modern uses of the windmill, *Engineering Magazine*, Feb. 1893, says: The best mills cost from about \$600 for the 10-ft. wheel of  $\frac{1}{8}$  horse-power to \$1200 for the 25-ft. wheel of  $1\frac{1}{2}$  horse-power or less. In the estimates a working-day of 8 hours is assumed; but the machine, when used for pumping, its most common application, may actually do its work 24 hours a day for days, weeks, and even months together, whenever the wind is "stiff" enough to turn it. It costs, for work done in situations in which its irregularity of action is no objection, only one half or one third as much as steam, hot-air, and gas engines of similar power. At Faversham, it is said, a 15-horse-power mill raises 2,000,000 gallons a month from a depth of 100 ft., saving 10 tons of coal a month, which would otherwise be expended in doing the work by steam.

Electric storage and lighting from the power of a windmill has been tested on a large scale for several years by Charles F. Brush, at Cleveland, Ohio. In 1887 he erected on the grounds of his dwelling a windmill 56 ft. in diameter, that operates with ordinary wind a dynamo at 500 revolutions per minute, with an output of 12,000 watts—16 electric horse-power—charging a storage system that gives a constant lighting capacity of 100 16 to 20 candle-power lamps. The current from the dynamo is automatically regulated to commence charging at 330 revolutions and 70 volts, and cutting the circuit at 75 volts. Thus, by its 24 hours' work, the storage system of 408 cells in 12 parallel series, each cell having a capacity of 100 ampère hours, is kept in constant readiness for all the requirements of the establishment, it being fitted up with 350 incandescent lamps, about 100 being in use each evening. The plant runs at a mere nominal expense for oil, repairs, and attention. (For a fuller description of this plant, and of a more recent one at Marblehead Neck, Mass., see Lieut. Lewis's paper in *Engineering Magazine*, Dec. 1894, p. 475.)

## COMPRESSED AIR.

**Heating of Air by Compression.**—Kimball, in his treatise on Physical Properties of Gases, says: When air is compressed, all the work which is done in the compression is converted into heat, and shows itself in the rise in temperature of the compressed gas. In practice many devices are employed to carry off the heat as fast as it is developed, and keep the temperature down. But it is not possible in any way to totally remove this difficulty. But, it may be objected, if all the work done in compression is converted into heat, and if this heat is got rid of as soon as possible, then the work may be virtually thrown away, and the compressed air can have no more energy than it had before compression. It is true that the compressed gas has no more energy than the gas had before compression, if its temperature is no higher, but the advantage of the compression lies in bringing its energy into more available form.

The total energy of the compressed and uncompressed gas is the same at the same temperature, but the available energy is much greater in the former.

When the compressed air is used in driving a rock-drill, or any other piece of machinery, it gives up energy equal in amount to the work it does, and its temperature is accordingly greatly reduced.

**Causes of Loss of Energy in Use of Compressed Air.** (Zahner, on Transmission of Power by Compressed Air.)—1. The compression of air always develops heat, and as the compressed air always cools down to the temperature of the surrounding atmosphere before it is used, the mechanical equivalent of this dissipated heat is work lost.

2. The heat of compression increases the volume of the air, and hence it is necessary to carry the air to a higher pressure in the compressor in order that we may finally have a given volume of air at a given pressure, and at the temperature of the surrounding atmosphere. The work spent in effecting this excess of pressure is work lost.

3. Friction of the air in the pipes, leakage, dead spaces, the resistance offered by the valves, insufficiency of valve-area, inferior workmanship, and slovenly attendance, are all more or less serious causes of loss of power.

The first cause of loss of work, namely, the heat developed by compression, is entirely unavoidable. The whole of the mechanical energy which the compressor-piston spends upon the air is converted into heat. This heat is dissipated by conduction and radiation, and its mechanical equivalent is work lost. The compressed air, having again reached thermal equilibrium with the surrounding atmosphere, expands and does work in virtue of its intrinsic energy.

The intrinsic energy of a fluid is the energy which it is capable of exerting against a piston in changing from a given state as to temperature and volume to a total privation of heat and indefinite expansion.

**Adiabatic and Isothermal Compression.**—Air may be compressed either *adiabatically*, in which all the heat resulting from compression is retained in the air compressed, or *isothermally*, in which the heat is removed as rapidly as produced, by means of some form of refrigerator.

**Volumes, Mean Pressures per Stroke, Temperatures, etc., in the Operation of Air-compression from 1 Atmosphere and 60° Fahr.** (F. Richards, *Am. Mach.*, March 30, 1893.)

Column 3 gives the volume of air after compression to the given pressure and after it is cooled to its initial temperature. After compression air loses its heat very rapidly, and this column may be taken to represent the volume of air after compression available for the purpose for which the air has been compressed.

Column 4 gives the volume of air more nearly as the compressor has to deal with it. In any compressor the air will lose some of its heat during compression. The slower the compressor runs the cooler the air and the smaller the volume.

Column 5 gives the mean effective resistance to be overcome by the air-cylinder piston in the stroke of compression, supposing the air to remain constantly at its initial temperature. Of course it will not so remain, but this column is the ideal to be kept in view in economical air-compression.

Column 6 gives the mean effective resistance to be overcome by the piston, supposing that there is no cooling of the air. The actual mean effective pressure will be somewhat less than as given in this column; but for computing the actual power required for operating air-compressor cylinders the figures in this column may be taken and a certain percentage added—say 10 per cent—and the result will represent very closely the power required by the compressor.

The mean pressures given being for compression from one atmosphere upward, they will not be correct for computations in compound compression or for any other initial pressure.

**Loss Due to Excess of Pressure caused by Heating in the Compression-cylinder.**—If the air during compression were kept at a constant temperature, the compression-curve of an indicator-diagram taken from the cylinder would be an isothermal curve, and would follow the law of Boyle and Marriotte,  $p v = a$  constant, or  $p_1 v_1 = p_0 v_0$ , or

$p_1 = p_0 \frac{v_0}{v_1}$ ,  $p_0$  and  $v_0$  being the pressure and volume at the beginning of compression, and  $p_1 v_1$  the pressure and volume at the end, or at any intermediate point. But as the air is heated during compression the pressure increases faster than the volume decreases, causing the work required for any given pressure to be increased. If none of the heat were abstracted by radiation or by injection of water, the curve of the diagram would be an adiabatic curve, with the equation  $p_1 = p_0 \left( \frac{v_0}{v_1} \right)^{1.405}$ . Cooling the air dur-

ing compression, or compressing it in two cylinders, called compounding, and cooling the air as it passes from one cylinder to the other, reduces the exponent of this equation, and reduces the quantity of work necessary to effect a given compression. F. T. Gause (*Am. Mach.*, Oct. 20, 1892), describing the operations of the Popp air-compressors in Paris, says: The greatest saving realized in compressing in a single cylinder was 33 per cent of that theoretically possible. In cards taken from the 2000 H.P. compound compressor at Quai De La Gare, Paris, the saving realized is 85 per cent of the theoretical amount. Of this amount only 8 per cent is due to cooling during compression, so that the increase of economy in the compound compressor is mainly due to cooling the air between the two stages of compression. A compression-curve with exponent 1.25 is the best result that was obtained for compression in a single cylinder and cooling with a very fine spray. The curve with exponent 1.15 is that which must be realized in a single cylinder to equal the present economy of the compound compressor at Quai De La Gare.

**Horse-power required to compress and deliver one cubic foot of Free Air** per minute to a given pressure with no cooling of the air during the compression; also the horse-power required, supposing the air to be maintained at constant temperature during the compression.

**Horse-power required to compress and deliver one cubic foot of Compressed Air** per minute at a given pressure with no cooling of the air during the compression; also the horse-power required, supposing the air to be maintained at constant temperature during the compression.

Gauge-pressure.	Air not cooled.	Air constant temperature.	Gauge-pressure.	Air not cooled.	Air constant temperature.
5	.0196	.0188	5	.0263	.0251
10	.0361	.0333	10	.0606	.0559

The horse-power given above is the theoretical power, no allowance being made for friction of the compressor or other losses, which may amount to 10 per cent or more.

### Formulae for Adiabatic Compression or Expansion of Air (or other sensibly perfect gas).

Let air at an absolute temperature  $T_1$ , absolute pressure  $p_1$ , and volume  $v_1$  be compressed to an absolute pressure  $p_2$  and corresponding volume  $v_2$  and absolute temperature  $T_2$ ; or let compressed air of an initial pressure, volume, and temperature  $p_2$ ,  $v_2$ , and  $T_2$  be expanded to  $p_1$ ,  $v_1$ , and  $T_1$ , there being no transmission of heat from or into the air during the operation. Then the following equations express the relations between pressure, volume, and temperature (see works on Thermodynamics):

$$\frac{v_1}{v_2} = \left(\frac{p_2}{p_1}\right)^{0.711}; \quad \frac{p_2}{p_1} = \left(\frac{v_1}{v_2}\right)^{1.41}, \quad \frac{v_1}{v_2} = \left(\frac{T_2}{T_1}\right)^{2.46};$$

$$\frac{T_2}{T_1} = \left(\frac{v_1}{v_2}\right)^{0.41}; \quad \frac{T_2}{T_1} = \left(\frac{p_2}{p_1}\right)^{0.29}; \quad \frac{p_2}{p_1} = \left(\frac{T_2}{T_1}\right)^{3.46}.$$

The exponents are derived from the ratio  $cp \div cv = k$  of the specific heats of air at constant pressure and constant volume. Taking  $k = 1.406$ ,  $1 \div k = 0.711$ ;  $k - 1 = 0.406$ ;  $1 \div (k - 1) = 2.463$ ;  $k \div (k - 1) = 3.463$ ;  $(k - 1) \div k = 0.289$ .

**Work of Adiabatic Compression of Air.**—If air is compressed in a cylinder without clearance from a volume  $v_1$  and pressure  $p_1$  to a smaller volume  $v_2$  and higher pressure  $p_2$ , work equal to  $p_1 v_1$  is done by the external air on the piston while the air is drawn into the cylinder. Work is then done by the piston on the air, first, in compressing it to the pressure  $p_2$  and volume  $v_2$ , and then in expelling the volume  $v_2$  from the cylinder against the pressure  $p_2$ . If the compression is adiabatic,  $p_1 v_1^k = p_2 v_2^k = \text{constant}$ .  $k = 1.41$ .

The work of compression of 1 pound of air is

$$\frac{p_1 v_1}{k - 1} \left\{ \left(\frac{v_1}{v_2}\right)^{k-1} - 1 \right\} = \frac{p_1 v_1}{k - 1} \left\{ \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} - 1 \right\}$$

or

$$2.463 p_1 v_1 \left\{ \left(\frac{v_1}{v_2}\right)^{0.41} - 1 \right\} = 2.463 p_1 v_1 \left\{ \left(\frac{p_2}{p_1}\right)^{0.29} - 1 \right\}.$$

The work of expulsion is  $p_2 v_2 = p_1 v_1 \left(\frac{p_2}{p_1}\right)^{0.29}$ .

The total work is the sum of the work of compression and expulsion less the work done on the piston during admission, and it equals

$$p_1 v_1 \left\{ \frac{k}{k-1} \left\{ \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} - 1 \right\} \right\} = 3.463 p_1 v_1 \left\{ \left(\frac{p_2}{p_1}\right)^{0.29} - 1 \right\}.$$

The mean effective pressure during the stroke is

$$p_1 \frac{k}{k-1} \left\{ \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} - 1 \right\} = 3.463 p_1 \left\{ \left(\frac{p_2}{p_1}\right)^{0.29} - 1 \right\}.$$

$p_1$  and  $p_2$  are absolute pressures above a vacuum in atmospheres or in pounds per square inch or per square foot.

**EXAMPLE.**—Required the work done in compressing 1 cubic foot of air per second from 1 to 6 atmospheres, including the work of expulsion from the cylinder.

$p_2 \div p_1 = 6$ ;  $6^{0.29} - 1 = 0.681$ ;  $3.463 \times 0.681 = 2.358$  atmospheres,  $\times 14.7 = 34.66$  lbs. per sq. in. mean effective pressure,  $\times 144 = 4991$  lbs. per sq. ft.,  $\times 1$  ft. stroke = 4991 ft.-lbs.,  $\div 550$  ft.-lbs. per second = 9.08 H.P.

If  $R = \text{ratio of pressures} = p_2 \div p_1$ , and if  $v_1 = 1$  cubic foot, the work done in compressing 1 cubic foot from  $p_1$  to  $p_2$  is in foot-pounds

$$3.463p_1(R^{0.29} - 1),$$

$p_1$  being taken in lbs. per sq. ft. For compression at the sea-level  $p_1$  may be taken at 14 lbs. per sq. in. = 2016 lbs. per sq. ft., as there is some loss of pressure due to friction of valves and passages.

Indicator-cards from compressors in good condition and under working-speeds usually follow the adiabatic line closely. A low curve indicates piston leakage. Such cooling as there may be from the cylinder-jacket and the re-expansion of the air in clearance-spaces tends to reduce the mean effective pressure, while the "camel-backs" in the expulsion-line, due to resistance to opening of the discharge-valve, tend to increase it.

Work of one stroke of a compressor, with adiabatic compression, in foot-pounds,

$$W = 3.463P_1V_1(R^{0.29} - 1),$$

in which  $P_1 = \text{initial absolute pressure in lbs. per sq. ft.}$  and  $V_1 = \text{volume traversed by piston in cubic feet.}$

The work done during adiabatic compression (or expansion) of 1 pound of air from a volume  $v_1$  and pressure  $p_1$  to another volume  $v_2$  and pressure  $p_2$  is equal to the mechanical equivalent of the heating (or cooling). If  $t_1$  is the higher and  $t_2$  the lower temperature, Fahr., the work done is  $c_v J(t_1 - t_2)$  foot-pounds,  $c_v$  being the specific heat of air at constant volume = 0.1689 and  $J = 778$ ,  $c_v J = 131.4$ .

The work during compression also equals

$$\frac{c_v J}{Ra} p_1 v_1 \left[ \left( \frac{p_2}{p_1} \right)^{0.29} - 1 \right] = 2.463 p_1 v_1 \left\{ \left( \frac{p_2}{p_1} \right)^{0.29} - 1 \right\},$$

$Ra$  being the value of  $p v \div \text{absolute temperature for 1 pound of air} = 53.37$ .

The work during expansion is

$$2.463 p_1 v_1 \left[ 1 - \left( \frac{p_2}{p_1} \right)^{0.29} \right] = 2.463 p_2 v_2 \left[ \left( \frac{p_1}{p_2} \right)^{0.29} - 1 \right],$$

in which  $p_1 v_1$  are the initial and  $p_2 v_2$  the final pressures and volumes.

**Compressed-air Engines, Adiabatic Expansion.** — Let the initial pressure and volume taken into the cylinder be  $p_1$  lbs. per sq. ft. and  $v_1$  cubic feet; let expansion take place to  $p_2$  and  $v_2$  according to the adiabatic law  $p_1 v_1^{1.41} = p_2 v_2^{1.41}$ ; then at the end of the stroke let the pressure drop to the back-pressure  $p_3$ , at which the air is exhausted. Assuming no clearance, the work done by one pound of air during admission, measured above vacuum, is  $p_1 v_1$ , the work during expansion is  $2.463 p_1 v_1 \left[ 1 - \left( \frac{p_2}{p_1} \right)^{0.29} \right]$ , and the negative or back-pressure work is  $-p_3 v_2$ .

The total work is  $p_1 v_1 + 2.463 p_1 v_1 \left[ 1 - \left( \frac{p_2}{p_1} \right)^{0.29} \right] - p_3 v_2$ , and the mean effective pressure is the total work divided by  $v_2$ .

If the air is expanded down to the back-pressure  $p_3$  the total work is

$$3.463 p_1 v_1 \left\{ 1 - \left( \frac{p_3}{p_1} \right)^{0.29} \right\}$$

or, in terms of the final pressure and volume,

$$3.463 p_3 v_2 \left\{ \left( \frac{p_1}{p_3} \right)^{0.29} - 1 \right\},$$

and the mean effective pressure is

$$3.463 p_3 \left\{ \left( \frac{p_1}{p_3} \right)^{0.29} - 1 \right\}.$$

The actual work is reduced by clearance. When this is considered, the product of the initial pressure  $p_1$  by the clearance volume is to be subtracted from the total work calculated from the initial volume  $v_1$  including clearance. (See p. 744, under "Steam-engine.")

**Mean Effective Pressures of Air Compressed Adiabatically.**  
(F. A. Halsey, *Am. Mach.*, Mar. 10, 1898.)

4.25	1.521	25.2	8.	1.827	39.9
4.5	1.546	26.4			

*R* = final ÷ initial absolute pressure.

MEP = mean effective pressure, lbs. per sq. in., based on 14 lbs. initial.

**Compound Compression, with Air Cooled between the Two Cylinders.** (*Am. Mach.*, March 10 and 31, 1898.)—Work in low-pressure cylinder =  $W_1$ , in high-pressure cylinder  $W_2$ . Total work

$$W_1 + W_2 = 3.46P_1V_1[r_1^{.29} + R^{.29}r_1^{-.29} - 2].$$

$r_1$  = ratio of pressures in l. p. cyl.,  $r_2$  = ratio in h. p. cyl.,  $R = r_1r_2$ . When  $r_1 = r_2 = \sqrt{R}$ , the sum  $W_1 + W_2$  is a minimum. Hence for a given total ratio of pressures,  $R$ , the work of compression will be least when the ratios of the pressures in each of the two cylinders are equal.

The equation may be simplified, when  $r_1 = \sqrt{R}$ , to the following:

$$W_1 + W_2 = 6.92P_1V_1[R^{0.145} - 1].$$

Dividing by  $V_1$  gives the mean effective pressure reduced to the low-pressure cylinder  $MEP = 6.92P_1[R^{0.145} - 1]$ .

In the above equation the compression in each cylinder is supposed to be adiabatic, but the intercooler is supposed to reduce the temperature of the air to that at which compression began.

**Mean Effective Pressures of Air Compressed in Two Stages, assuming the Intercooler to Reduce the Temperature to That at which Compression Began.** (F. A. Halsey, *Am. Mach.*, Mar. 31, 1898.)

<i>R</i>	$R^{0.145}$	MEP from 14 lbs. Initial.	Ultimate Saving by Com- pound- ing, %	<i>R</i>	$R^{0.145}$	MEP from 14 lbs. Initial.	Ultimate Saving by Com- pound- ing, %

*R* = final ÷ initial absolute pressure.

MEP = mean effective pressure lbs. per sq. in. based on 14 lbs. absolute initial pressure reduced to the low-pressure cylinder.

**To Find the Index of the Curve of an Air-diagram.**—If  $P_1V_1$  be pressure and volume at one point on the curve, and  $PV$  the pressure and volume at another point, then  $\frac{P}{P_1} = \left(\frac{V_1}{V}\right)^x$ , in which  $x$  is the index to be found. Let  $P \div P_1 = R$ , and  $V_1 \div V = r$ ; then  $R = r^x$   $\log R = x \log r$ , whence  $x = \log R \div \log r$ .

The pressures in the table are all gauge-pressures except those in italics, which are absolute pressures (above a vacuum).

**Mountain or High-altitude Compressors.**

(Norwalk Iron Works Co.)

Diameter Air-cylinder.	Length of Stroke.	Diameter of Compressing Cylinder.	Diameter of Steam-cylinder.	Revolutions per minute.	At Sea-level.		At 2000 feet.		At 6000 feet.		At 10,000 feet.	
					Capacity. cubic feet.	Horse-power.	Capacity.	Horse-power.	Capacity.	Horse-power.	Capacity.	Horse-power.
12	12	7	10	190	298	35	280	34	244	32	214	30
16	16	9 $\frac{1}{2}$	14	150	558	70	524	68	462	64	405	60
20	20	13 $\frac{1}{2}$	18	120	872	110	819	107	722	100	624	94
22	24	13 $\frac{1}{2}$	20	110	1160	145	1090	140	960	132	843	124
26	30	17 $\frac{1}{2}$	24	90	1659	215	1560	207	1373	195	1200	184

As the capacity decreases in a greater ratio than the power necessary to compress, it follows that operations at a high altitude are more expensive than at sea-level. At 10,000 feet this extra expense amounts to over 20 per cent.

**Compressed-air Table for Pumping Plants.**  
(Ingersoll-Sergeant Drill Co.)

For the convenience of engineers and others figuring on pumping plants to be operated by compressed air, we subjoin a table by which the pressure and volume of air required for any size pump can be readily ascertained. Reasonable allowances have been made for loss due to clearances in pump and friction in pipe.

Ratio of Diameters.	Perpendicular Height, in Feet, to which the Water is to be Pumped.

A = air-pressure at pump. B = cubic feet of free air per gallon of water.

To find the amount of air and pressure required to pump a given quantity of water a given height, find the ratio of diameters between water and air cylinders, and multiply the number of gallons of water by the figure found in the column for the required lift. The result is the number of *cubic feet of free air*. The pressure required on the pump will be found directly above in the same column. For example: The ratio between cylinders being 2 to 1, required to pump 100 gallons, height of lift 250 feet. We find under 250 feet at ratio 2 to 1 the figures 2.11; 2.11 × 100 = 211 cubic feet of free air. The pressure required is 34.38 pounds.

**Compressed-air Table for Hoisting-engines.**

(Ingersoll-Sergeant Drill Co.)

The following table gives an approximate idea of the volume of free air required for operating hoisting-engines, the air being delivered at 60 lbs. gauge-pressure. There are so many variable conditions to the operation of hoisting-engines in common use that accurate computations can only be offered when fixed data are given. In the table the engine is assumed to actually run but one-half of the time for hoisting, while the compressor, of course, runs continuously. If the engine runs less than one-half the time, as it usually does, the volume of air required will be proportionately less, and *vice versa*. The table is computed for maximum loads, which also in practice may vary widely. From the intermittent character of the work of a hoisting-engine the parts are able to resume their normal temperature between the hoists, and there is little probability of the annoyance of freezing up the exhaust-passages.

**VOLUME OF FREE AIR REQUIRED FOR OPERATING HOISTING-ENGINES, THE AIR COMPRESSED TO 60 POUNDS GAUGE-PRESSURE.****SINGLE-CYLINDER HOISTING-ENGINE.**

**Practical Results with Compressed Air.**—*Compressed-air System at the Chapin Mines, Iron Mountain, Mich.*—These mines are three miles from the falls which supply the power. There are four turbines at the falls, one of 1000 horse-power and three of 900 horse-power each. The pressure is 60 pounds at 60° Fahr. Each turbine runs a pair of compressors. The pipe to the mines is 24 ins. diameter. The power is applied at the mines to Corliss engines, running pumps, hoists, etc., and direct to rock-drills.

A test made in 1888 gave 1430.27 H.P. at the compressors, and 390.17 H.P. as the sum of the horse-power of the engines at the mines. Therefore, only 27% of the power generated was recovered at the mines. This includes the loss due to leakage and the loss of energy in heat, but not the friction in the engines or compressors. (F. A. Pocock, Trans. A. I. M. E., 1890.)

W. L. Saunders (*Jour. F. I.* 1892) says: "There is not a properly designed compressed-air installation in operation to-day that loses over 5% by transmission alone. The question is altogether one of the size of pipe; and if the pipe is large enough, the friction loss is a small item.

"The loss of power in common practice, where compressed air is used to drive machinery in mines and tunnels, is about 70%. In the best practice, with the best air-compressors, and without reheating, the loss is about 60%. These losses may be reduced to a point as low as 20% by combining the best systems of reheating with the best air-compressors."

**Gain due to Reheating.**—Prof. Kennedy says compressed-air transmission system is now being carried on, on a large commercial scale, in such a fashion that a small motor four miles away from the central station can indicate in round numbers 10 horse-power, for 20 horse-power at the station itself, allowing for the value of the coke used in heating the air.

The limit to successful reheating lies in the fact that air-engines cannot work to advantage at temperatures over 350°.

The efficiency of the common system of reheating is shown by the results obtained with the Popp system in Paris. Air is admitted to the reheater at about 83°, and passes to the engine at about 315°, thus being increased in volume about 42%. The air used in Paris is about 11 cubic feet of free air per minute per horse-power. The ordinary practice in America with cold air is from 15 to 25 cubic feet per minute per horse-power. When the Paris engines were worked without reheating the air consumption was increased to about 15 cubic feet per horse-power per minute. The amount of fuel consumed during reheating is trifling.

**Efficiency of Compressed-air Engines.**—The efficiency of an air-engine, that is, the percentage which the power given out by the air-engine bears to that required to compress the air in the compressor, depends on the loss by friction in the pipes, valves, etc., as well as in the engine itself. This question is treated at length in the catalogue of the Norwalk Iron Works Co., from which the following is condensed. As the friction increases the most economical pressure increases. In fact, for any given friction in a pipe, the pressure at the compressor must not be carried below a certain limit. The following table gives the lowest pressures which should be used at the compressor with varying amounts of friction in the pipe:

Friction, lbs. ....	2.9	5.8	8.8	11.7	14.7	17.6	20.5	23.5	26.4	29.4
Lbs. at Compressor...	20.5	29.4	38.2	47.	52.8	61.7	70.5	76.4	82.3	88.2
Efficiency %.....	70.9	64.5	60.6	57.9	55.7	54.0	52.5	51.3	50.2	49.2

An increase of pressure will decrease the bulk of air passing the pipe and its velocity. This will decrease the loss by friction, but we subject ourselves to a new loss, *i.e.* the diminishing efficiencies of increasing pressures. Yet as each cubic foot of air is at a higher pressure and therefore carries more power, we will not need as many cubic feet as before, for the same work. With so many sources of gain or loss, the question of selecting the proper pressure is not to be decided hastily.

The losses are, first, friction of the compressor. This will amount ordinarily to 15 or 20 per cent, and cannot probably be reduced below 10 per cent. Second, the loss occasioned by pumping the air of the engine-room, rather than the air drawn from a cooler place. This loss varies with the season and amounts from 3 to 10 per cent. This can all be saved. The third loss, or series of losses, arises in the compressing cylinder, *viz.*, insufficient supply, difficult discharge, defective cooling arrangements, poor lubrication, etc. The fourth loss is found in the pipe. This loss varies with the situation, and is subject to somewhat complex influences. The fifth loss is chargeable to fall of temperature in the cylinder of the air-engine. Losses arising from leaks are often serious.

**Effect of Temperature of Intake upon the Discharge of a Compressor.**—Air should be drawn from outside the engine-room, and from as cool a place as possible. The gain amounts to one per cent for every five degrees that the air is taken in lower than the temperature of the engine-room. The inlet conduit should have an area at least 50% of the area of the air-piston, and should be made of wood, brick, or other non-conductor of heat.

Discharge of a compressor having an intake capacity of 1000 cubic feet per minute, and volumes of the discharge reduced to cubic feet at atmospheric pressure and at temperature of 62 degrees Fahrenheit:

Temperature of Intake, F.....	0°	32°	62°	75°	80°	90°	100°	110°
Relative volume discharged, cubic ft...	1135	1060	1000	975	966	949	932	916

**Requirements of Rock-drills Driven by Compressed Air.** (Norwalk Iron Works Co.)—The speed of the drill, the pressure of air, and the nature of the rock affect the consumption of power of drills.

A three-inch drill using air at 30 lbs. pressure made 300 blows per minute and consumed the equivalent of 64 cubic feet of free air per minute. The same drill, with air of 58 lbs. pressure, made 450 blows per minute and consumed 160 cubic feet of free air per minute. At Hell Gate different

machines doing the same work used from 80 to 150 cubic feet free air per minute.

An average consumption may be taken generally from 80 to 100 cubic feet per minute, according to the nature of the work.

**The Popp Compressed-air System in Paris.**—A most extensive system of distribution of power by means of compressed air is that of M. Popp, in Paris. One of the central stations is laid out for 24,000 horse-power. For a very complete description of the system, see *Engineering*, Feb. 15, June 7, 21, and 28, 1889, and March 13 and 20, April 10, and May 1, 1891. Also *Proc. Inst. M. E.*, July, 1889. A condensed description will be found in *Modern Mechanism*, p. 12.

**Utilization of Compressed Air in Small Motors.**—In the earliest stages of the Popp system in Paris it was recognized that no good results could be obtained if the air were allowed to expand direct into the motor; not only did the formation of ice due to the expansion of the air rapidly accumulate and choke the exhaust, but the percentage of useful work obtained, compared with that put into the air at the central station, was so small as to render commercial results hopeless.

After a number of experiments M. Popp adopted a simple form of cast-iron stove lined with fire-clay, heated either by a gas jet or by a small coke fire. This apparatus answered the desired purpose until some better arrangement was perfected, and the type was accordingly adopted throughout the whole system. The economy resulting from the use of an improved form was very marked, as will be seen from the following table.

EFFICIENCY OF AIR-HEATING STOVES.

	Cast-iron Box Stoves.		Wrought-iron Coiled Tubes.
Heating surface, sq. ft.....	14	14	46.3
Air heated per hour, cu. ft.....	20,342	11,654	38,428
Temp. of air admitted to oven, deg. F.....	45	45	41
"    "    at exit, deg. F.....	215	361	347
Total heat absorbed per hour, calories.....	17,900	17,200	39,200
Do. per sq. ft. of heating surface per hour, cal.	1,278	1,228	830
Do. per lb. of coke.....	2,032	2,058	2,545

The results given in this table were obtained from a large number of trials. From these trials it was found that more than 70% of the total number of calories in the fuel employed was absorbed by the air and transformed into useful work. Whether gas or coal be employed as the fuel, the amount required is so small as to be scarcely worth consideration; according to the experiments carried out it does not exceed 0.2 lb. per horse-power per hour, but it is scarcely to be expected that in regular practice this quantity is not largely exceeded. The efficiency of fuel consumed in this way is at least six times greater than when utilized in a boiler and steam-engine.

According to Prof. Riedler, from 15% to 20% above the power at the central station can be obtained by means at the disposal of the power users, and it has been shown by experiment that by heating the air to 480° F. an increased efficiency of 30% can be obtained.

A large number of motors in use among the subscribers to the Compressed Air Company of Paris are rotary engines developing 1 horse-power and less, and these in the early times of the industry were very extravagant in their consumption. Small rotary engines, working cold air without expansion, used as high as 2330 cu. ft. of air per brake horse-power per hour, and with heated air 1624 cu. ft. Working expansively, a 1 horse-power rotary engine used 1469 cu. ft. of cold air, or 960 cu. ft. of heated air, and a 2-horse-power rotary engine 1059 cu. ft. of cold air, or 847 cu. ft. of air, heated to about 50° C.

The efficiency of this type of rotary motors, with air heated to 50° C., may now be assumed at 43%. With such an efficiency the use of small motors in many industries becomes possible, while in cases where it is necessary to have a constant supply of cold air economy ceases to be a matter of the first importance.

Tests of a small Riedinger rotary engine, used for driving sewing-machines and indicating about 0.1 H.P. showed an air-consumption of 1377 cu. ft. per

H P. per hour when the initial pressure of the air was 86 lbs. per sq. in. and its temperature 54° F., and 988 cu. ft. when the air was heated to 338° F., its pressure being 72° lbs. With a one-half horse-power variable-expansion rotary engine the air-consumption was from 800 to 900 cu. ft. per H.P. per hour for initial pressures of 54 to 85 lbs. per sq. in. with the air heated from 336° to 388° F., and 1148 cu. ft. with cold air, 46° F., and an initial pressure of 72 lbs. The volumes of air were all taken at atmospheric pressure.

Trials made with an old single-cylinder 80-horse-power Farcot steam-engine, indicating 72 horse-power, gave a consumption of air per brake horse-power as low as 465 cu. ft. per hour. The temperature of admission was 320° F., and of exhaust 95° F.

Prof. Elliott gives the following as typical results of efficiency for various systems of compressors and air-motors :

Simple compressor and simple motor, efficiency .....	39.1%
Compound compressor and simple motor, " .....	44.9
“ “ “ compound motor, efficiency.....	50.7
Triple compressor and triple motor, “ .....	55.3

The efficiency is the ratio of the indicated horse-power in the motor cylinders to the indicated horse-power in the steam-cylinders of the compressor. The pressure assumed is 6 atmospheres absolute, and the losses are equal to those found in Paris over a distance of 4 miles.

### **Summary of Efficiencies of Compressed-air Transmission at Paris, between the Central Station at St. Fargeau and a 10-horse-power Motor Working with Pressure Reduced to $4\frac{1}{2}$ Atmospheres.**

(The figures below correspond to mean results of two experiments cold and two heated.)

1 indicated horse-power at central station gives 0.845 indicated horse-power in compressors, and corresponds to the compression of 348 cubic feet of air per hour from atmospheric pressure to 6 atmospheres absolute. (The weight of this air is about 25 pounds.)

0.845 indicated horse-power in compressors delivers as much air as will do 0.52 indicated horse-power in adiabatic expansion after it has fallen in temperature to the normal temperature of the mains.

The fall of pressure in mains between central station and Paris (say 5 kilometres) reduces the possibility of work from 0.52 to 0.51 indicated horse-power.

The further fall of pressure through the reducing valve to  $4\frac{1}{2}$  atmospheres (absolute) reduces the possibility of work from 0.51 to 0.50.

Incomplete expansion, wire-drawing, and other such causes reduce the actual indicated horse-power of the motor from 0.50 to 0.39.

By heating the air before it enters the motor to about 320° F., the actual indicated horse-power at the motor is, however, increased to 0.54. The ratio of gain by heating the air is, therefore,  $0.54 \div 0.39 = 1.38$ .

In this process additional heat is supplied by the combustion of about 0.39 pounds of coke per indicated horse-power per hour, and if this be taken into account, the real indicated efficiency of the whole process becomes 0.47 instead of 0.54.

Working with cold air the work spent in driving the motor itself reduces the available horse-power from 0.39 to 0.26.

Working with heated air the work spent in driving the motor itself reduces the available horse-power from 0.54 to 0.44.

A summary of the efficiencies is as follows :

Efficiency of main engines 0.845.

Efficiency of compressors  $0.52 \div 0.845 = 0.61$ .

Efficiency of transmission through mains  $0.51 \div 0.52 = 0.98$ .

Efficiency of reducing valve  $0.50 \div 0.51 = 0.98$ .

The combined efficiency of the mains and reducing valve between 5 and  $4\frac{1}{2}$  atmospheres is thus  $0.98 \times 0.98 = 0.96$ . If the reduction had been to 4,  $3\frac{1}{2}$ , or 3 atmospheres, the corresponding efficiencies would have been 0.93, 0.89, and 0.85 respectively.

Indicated efficiency of motor  $0.39 \div 0.50 = 0.78$ .

Indicated efficiency of whole process with cold air 0.39. Apparent indicated efficiency of whole process with heated air 0.54.

Real indicated efficiency of whole process with heated air 0.47.

Mechanical efficiency of motor, cold, 0.67.

Mechanical efficiency of motor, hot, 0.81.

Most of the compressed air in Paris is used for driving motors, but the work done by these is of the most varied kind. A list of motors driven from St. Fargeau station shows 225 installations, nearly all motors working at from  $\frac{1}{8}$  horse-power to 50 horse-power, and the great majority of them more than two miles away from the station. The new station at Quai de la Gare is much larger than the one at St. Fargeau. Experiments on the Riedler air-compressors at Paris, made in December, 1891, to determine the ratio between the indicated work done by the air-pistons and the indicated work in the steam-cylinders, showed a ratio of 0.8997. The compressors are driven by four triple-expansion Corliss engines of 2000 horse-power each.

**Shops Operated by Compressed Air.**—The *Iron Age*, March 2, 1893, describes the shops of the Wuerpel Switch and Signal Co., East St. Louis, the machine tools of which are operated by compressed air, each of the larger tools having its own air engine, and the smaller tools being belted from shafting driven by an air engine. Power is supplied by a compound compressor rated at 55 horse-power. The air engines are of the Kriebel make, rated from 2 to 8 horse-power.

**Pneumatic Postal Transmission.**—A paper by A. Falkenau, Eug's Club of Philadelphia, April 1894, entitled the "First United States Pneumatic Postal System," gives a description of the system used in London and Paris, and that recently introduced in Philadelphia between the main post-office and a substation. In London the tubes are  $2\frac{1}{4}$  and 3 inch lead pipes laid in cast-iron pipes for protection. The carriers used in  $2\frac{1}{4}$ -inch tubes are but  $1\frac{1}{4}$  inches diameter, the remaining space being taken up by packing. Carriers are despatched singly. First, vacuum alone was used; later, vacuum and compressed air. The tubes used in the Continental cities in Europe are wrought iron, the Paris tubes being  $2\frac{1}{2}$  inches diameter. There the carriers are despatched in trains of six to ten, propelled by a piston. In Philadelphia the size of tube adopted is  $6\frac{1}{8}$  inches, the tubes being of cast iron bored to size. The lengths of the outgoing and return tubes are 2928 feet each. The pressure at the main station is 7 lbs., at the substation 4 lbs., and at the end of the return pipe atmospheric pressure. The compressor has two air-cylinders  $18 \times 24$  in. Each carrier holds about 200 letters, but 100 to 150 are taken as an average. Eight carriers may be despatched in a minute, giving a delivery of 48,000 to 72,000 letters per hour. The time required in transmission is about 57 seconds.

Pneumatic postal transmission tubes were laid in 1898 by the Batcheller Pneumatic Tube Co. between the general post-offices in New York and Brooklyn, crossing the East River on the bridge. The tubes are cast iron, 12-ft. lengths, bored to  $8\frac{1}{8}$  in. diameter. The joints are bells, calked with lead and yarn. There are two tubes, one operating in each direction. Both lines are operated by air-pressure above the atmospheric pressure. One tube is operated by an air-compressor in the New York office and the other by one located in the Brooklyn office.

The carriers are 24 in. long, in the form of a cylinder 7 in. in diameter, and are made of steel, with fibrous bearing-rings which fit the tube. Each carrier will contain about 600 ordinary letters, and they are despatched at intervals of 10 seconds in each direction, the time of transit between the two offices being  $3\frac{1}{2}$  minutes, the carriers travelling at a speed of from 30 to 35 miles per hour.

The air-compressors were built by the Rand Drill Co. and the Ingersoll-Sergeant Drill Co. The Rand Drill Co. compressor is of the duplex type and has two steam-cylinders  $10 \times 20$  in. and two air-cylinders  $24 \times 20$  in., delivering 1570 cu. ft. of free air per minute, at 75 revolutions, the power being about 50 H.P. Corliss valve-gear is on the steam cylinders and the Rand mechanical valve-gear on the air-cylinders.

The Ingersoll-Sergeant Drill Co. furnished two duplex Corliss air-compressors, with mechanically moved valves on air-cylinders. The steam-cylinders are  $14 \times 18$  in. and the air-cylinders  $26\frac{1}{4} \times 18$  in. They are designed for 80 to 90 revs. per min. and to compress to 20 lbs. per sq. in.

Another double line of pneumatic tubes has been laid between the main office and Postal Station H, Lexington Ave. and 44th St., in New York City. This line is about  $3\frac{1}{2}$  miles in length. There are three intermediate stations: Third Ave. and 8th St., Madison Square, and Third Ave. and 28th St. The carriers can be so adjusted when they are put into the tube that they will traverse the line and be discharged automatically from the tube at the station for which they are intended. The tubes are of the same size as those of the Brooklyn line and are operated in a similar manner. The initial air-compression is about 12 to 15 lbs. On the Brooklyn line it is about 7 lbs.

There is also a tube system between the New York Post-office and the Produce Exchange. For a very complete description of the system and its machinery see "The Pneumatic Despatch Tube System," by B. C. Batchelor. J. B. Lippincott Co., Philadelphia, 1897.

**The Mekarski Compressed-air Tramway at Berne, Switzerland.** (*Eng'g News*, April 20, 1893.)—The Mekarski system has been introduced in Berne, Switzerland, on a line about two miles long, with grades of 0.25% to 3.7% and 5.2%. The air is heated by passing it through superheated water at 330° F. It thus becomes saturated with steam, which subsequently partly condenses, its latent heat being absorbed by the expanding air. The pressure in the car reservoirs is 440 lbs. per sq. in.

The engine is constructed like an ordinary steam tramway locomotive, and drives two coupled axles, the wheel-base being 5.2 ft. It has a pair of outside horizontal cylinders, 5.1 × 8.6 in.; four coupled wheels, 27.5 in. diameter. The total weight of the car including compressed air is 7.25 tons, and with 30 passengers, including the driver and conductor, about 9.5 tons.

The authorized speed is about 7 miles per hour. Taking the resistance due to the grooved rails and to curves under unfavorable conditions at 30 lbs. per ton of car weight, the engine has to overcome on the steepest grade, 5%, a total resistance of about 0.63 ton, and has to develop 25 H.P. At the maximum authorized working pressure in cylinders of 176 lbs. per sq. in. the motors can develop a tractive force of 0.64 ton. This maximum is, therefore, just sufficient to take the car up the 5.2% grade, while on the flatter sections of the line the working pressure does not exceed 73 to 147 lbs. per sq. in. Sand has to be frequently used to increase the adhesion on the 2% to 5% grades.

Between the two car frames are suspended ten horizontal compressed-air storage-cylinders, varying in length according to the available space, but of uniform inside diameter of 17.7 in., composed of riveted 0.27-in. sheet iron, and tested up to 588 lbs. per sq. in. These cylinders have a collective capacity of 64.25 cu. ft., which, according to Mr. Mekarski's estimate, should have been sufficient for a double trip,  $3\frac{3}{4}$  miles. The trial trips, however, showed this estimate to be inadequate, and two further small storage-cylinders had therefore to be added of 5.3 cu. ft. capacity each, bringing the total cubic contents of the 12 storage-cylinders per car up to 75 cu. ft., divided into two groups, the working and the reserve battery, the former of 49 cu. ft. the latter of 26 cu. ft. capacity.

From the results of six official trips, the pressure and the mean consumption of air during a double journey per motor car are as follows:

Pressure of air in storage-cylinders at starting 440 lbs. per sq. in.; at end of up-journey 176 lbs., reserve 260 lbs.; at end of down-journey 103 lbs., reserve 176 lbs. Consumption of air during up-journey 92 lbs., during down-journey 31 lbs.

The working experience of 1891 showed that the air consumption per motor car for a double journey was from 103 to 154 lbs., mean 123 lbs., and per car mile from 28 to 42 lbs., mean 35 lbs.

The principal advantages of the compressed-air system for urban and suburban tramway traffic as worked at Berne consist in the smooth and noiseless motion; in the absence of smoke, steam, or heat, of overhead or underground conductors, of the more or less grinding motion of most electric cars, and of the jerky motion to which underground cable traction is subject. On all these grounds the system has vindicated its claims as being preferable to any other so far known system of mechanical traction for street tramways. Its disadvantages, on the other hand, consist in the extremely delicate adjustment of the different parts of the system, in the comparatively small supply of air carried by one motor car, which necessitates the car returning to the depot for refilling after a run of only four miles or 40 minutes, although on the Nogent and Paris lines the cars, which are, moreover, larger, and carry outside passengers on the top, run seven miles, and the loading pressure is 547 lbs. per sq. in. as against only 440 lbs. at Berne.

Longer distances in the same direction would involve either more powerful motors, a larger number of storage-cylinders, and consequently heavier cars, or loading stations every four or seven miles; and in this respect the system is manifestly inferior to electric traction, which easily admits of a line of 10 to 15 miles in length being continuously fed from one central station without the loss of time and expense caused by reloading.

The cost of working the Berne line is compared in the annexed table

with some other tramways worked under similar conditions by horse and mechanical traction for the year 1891.

For description of the Mekarski system as used at Nantes, France, see paper by Prof. D. S. Jacobs, *Trans. A. I. M. E.*, xix, 553.

**American Experiments on Compressed Air for Street Railways.**—Experiments have been made recently in Washington, D. C., and in New York City on the use of compressed air for street-railway traction. The air was compressed to 2000 lbs. per sq. in. and passed through a reducing-valve and a heater before being admitted to the engine. For an extended discussion of the relative merits of compressed air and electric traction, with an account of a test of a four-stage compressor giving a pressure of 2500 lbs. per sq. in., see *Eng'g News*, Oct. 7 and Nov. 4, 1897. A summarized statement of the probable efficiency of compressed-air traction is given as follows: Efficiency of compression to 2000 lbs. per sq. in. 65%. By wire-drawing to 100 lbs. 57.5% of the available energy of the air will be lost, leaving  $65 \times .425 = 27.625\%$  as the net efficiency of the air. This may be doubled by heating, making 55.25%, and if the motor has an efficiency of 80% the net efficiency of traction by compressed air will be  $55.25 \times .80 = 44.2\%$ . For a description of the Hardie compressed-air locomotive, designed for street-railway work, see *Eng'g News*, June 24, 1897. For use of compressed air in mine haulage, see *Eng'g News*, Feb. 10, 1898.

**Compressed Air for Working Underground Pumps in Mines.**—*Eng'g Record*, May 19, 1894, describes an installation of compressors for working a number of pumps in the Nottingham No. 15 Mine, Plymouth, Pa., which is claimed to be the largest in America. The compressors develop above 2300 H.P., and the piping, horizontal and vertical, is 6000 feet in length. About 25,000 gallons of water per hour are raised.

## FANS AND BLOWERS.

**Centrifugal Fans.**—The ordinary centrifugal fan consists of a number of blades fixed to arms, revolving on a shaft at high speed. The width of the blade is parallel to the axis of the shaft. Most engineers' reference books quote the experiments of W. Buckle, *Proc. Inst. M.E.*, 1847, as still standard. Mr. Buckle's conclusions are given below, together with data of more recent experiments.

Experiments were made as to the proper size of the inlet openings and on the proper proportions to be given to the vane. The inlet openings in the sides of the fan-chest were contracted from  $17\frac{1}{2}$  in., the original diameter, to 12 and 6 in. diam., when the following results were obtained:

First, that the power expended with the opening contracted to 12 in. diam. was as  $2\frac{1}{2}$  to 1 compared with the opening of  $17\frac{1}{2}$  in. diam.; the velocity of the fan being nearly the same, as also the quantity and density of air delivered.

Second, that the power expended with the opening contracted to 6 in. diam. was as  $2\frac{1}{2}$  to 1 compared with the opening of  $17\frac{1}{2}$  in. diam.; the velocity of the fan being nearly the same, and also the area of the efflux pipe, but the density of the air decreased one fourth.

These experiments show that the inlet openings must be made of sufficient size, that the air may have a free and uninterrupted action in its passage to the blades of the fan; for if we impede this action we do so at the expense of power.

With a vane 14 in. long, the tips of which revolve at the rate of 236.8 ft. per second, air is condensed to 9.4 ounces per square inch above the pressure of the atmosphere, with a power of 9.6 H. P.; but a vane 8 inches long, the diameter at the tips being the same, and having, therefore, the same velocity, condenses air to 6 ounces per square inch only, and takes 12 H. P.

Thus the density of the latter is little better than six tenths of the former, while the power absorbed is nearly 1.25 to 1. Although the velocity of the tips of the vanes is the same in each case, the velocities of the heels of the respective blades are very different, for, while the tips of the blades in each case move at the same rate, the velocity of the heel of the 14-inch is in the ratio of 1 to 1.67 to the velocity of the heel of the 8-inch blade. The longer blades approaching nearer the centre, strikes the air with less velocity, and allows it to enter on the blade with greater freedom, and with considerably less force than the shorter one. The inference is, that the short blade must take more power at the same time that it accumulates a less quantity of air. These experiments lead to the conclusion that the length of the vane demands as great a consideration as the proper diameter of the inlet opening. If there were no other object in view, it

would be useless to make the vanes of the fan of a greater width than the inlet opening can freely supply. On the proportion of the length and width of the vane and the diameter of the inlet opening rest the three most important points, viz., *quantity* and *density* of air, and expenditure of *power*.

In the 14-inch blade the tip has a velocity 2.6 times greater than the heel; and, by the laws of centrifugal force, the air will have a density 2.6 times greater at the tip of the blade than that at the heel. The air cannot enter on the heel with a density higher than that of the atmosphere; but in its passage along the vane it becomes compressed in proportion to its centrifugal force. The greater the length of the vane, the greater will be the difference of the centrifugal force between the heel and the tip of the blade; consequently the greater the density of the air.

Reasoning from these experiments, Mr. Buckle recommends for easy reference the following proportions for the construction of the fan:

1. Let the width of the vanes be one fourth of the diameter; 2. Let the diameter of the inlet openings in the sides of the fan-chest be one half the diameter of the fan; 3. Let the length of the vanes be one fourth of the diameter of the fan.

In adopting this mode of construction, the area of the inlet openings in the sides of the fan-chest will be the same as the circumference of the heel of the blade, multiplied by its width; or the same area as the space described by the heel of the blade.

### Best Proportions of Fans. (Buckle.)

PRESSURE FROM 3 OUNCES TO 6 OUNCES PER SQUARE INCH; OR 5.2 INCHES TO 10.4 INCHES OF WATER.

Diameter of Fan.		Vanes.		Diameter of Inlet Openings.	Diameter of Fan.		Vanes.		Diameter of Inlet Openings.						
		Width.	Length.				Width.	Length.							
ft.	ins.	ft.	ins.	ft.	ins.	ft.	ins.	ft.	ins.	ft.	ins.				
3	0	0	9	0	9	1	6	4	6	1	1½	1	1½	2	3
3	6	0	10½	0	10½	1	9	5	0	1	3	1	3	2	6
4	0	1	0	1	0	2	0	6	0	1	6	1	6	3	0

PRESSURE FROM 6 OUNCES TO 9 OUNCES PER SQUARE INCH, AND UPWARDS, OR 10.4 INCHES TO 15.6 INCHES OF WATER.

3	0	0	7	1	0	1	0	4	6	0	10½	1	4½	1	9
3	6	0	8½	1	1½	1	3	5	0	1	0	1	6	2	0
4	0	0	9½	1	3½	1	6	6	0	1	2	1	10	2	4

The dimensions of the above tables are not laid down as prescribed limits, but as approximations obtained from the best results in practice.

Experiments were also made with reference to the admission of air into the transit or outlet pipe. By a slide the width of the opening into this pipe was varied from 12 to 4 inches. The object of this was to proportion the opening to the quantity of air required, and thereby to lessen the power necessary to drive the fan. It was found that the less this opening is made, provided we produce sufficient blast, the less noise will proceed from the fan; and by making the tops of this opening level with the tips of the vane, the column of air has little or no reaction on the vanes.

The number of blades may be 4 or 6. The case is made of the form of an arithmetical spiral, widening the space between the case and the revolving blades, circumferentially, from the origin to the opening for discharge.

The following rules deduced from experiments are given in Spretson's treatise on Casting and Founding:

The fan-case should be an arithmetical spiral to the extent of the depth of the blade at least.

The diameter of the tips of the blades should be about double the diameter of the hole in the centre; the width to be about two thirds of the radius of the tips of the blades. The velocity of the tips of the blades should be rather

more than the velocity due to the air at the pressure required, say one eighth more velocity.

In some cases, two fans mounted on one shaft would be more useful than one wide one, as in such an arrangement twice the area of inlet opening is obtained as compared with a single wide fan. Such an arrangement may be adopted where occasionally half the full quantity of air is required, as one of them may be put out of gear, thus saving power.

**Pressure due to Velocity of the Fan-blades.**—"By increasing the number of revolutions of the fan the head or pressure is increased, the law being that the total head produced is equal (in centrifugal fans) to twice the height due to the velocity of the extremities of the blades, or

$$H = \frac{v^2}{g} \text{ approximately in practice" (W. P. Trowbridge, Trans. A. S. M. E.,$$

vii. 536.) This law is analogous to that of the pressure of a jet striking a plane surface. T. Hawksley, Proc. Inst. M. E., 1882, vol. lxix., says: "The pressure of a fluid striking a plane surface perpendicularly and then escaping at right angles to its original path is that due to twice the height  $h$  due the velocity."

(For discussion of this question, showing that it is an error to take the pressure as equal to a column of air of the height  $h = v^2 \div 2g$ , see Wolff on Windmills, p. 17.)

Buckle says: "From the experiments it further appears that the velocity of the tips of the fan is equal to nine tenths of the velocity a body would acquire in falling the height of a homogeneous column of air equivalent to the density." D. K. Clark (R. T. & D., p. 924), paraphrasing Buckle, apparently, says: "It further appears that the pressure generated at the circumference is one ninth greater than that which is due to the actual circumferential velocity of the fan." The two statements, however, are not in

harmony, for if  $v = 0.9 \sqrt{2gH}$ ,  $H = \frac{v^2}{0.81 \times 2g} = 1.234 \frac{v^2}{2g}$  and not  $1\frac{1}{9} \frac{v^2}{2g}$ .

If we take the pressure as that equal to a head or column of air of twice the height due the velocity, as is correctly stated by Trowbridge, the paradoxical statements of Buckle and Clark—which would indicate that the actual pressure is greater than the theoretical—are explained, and the

formula becomes  $H = .617 \frac{v^2}{g}$  and  $v = 1.273 \sqrt{gH} = 0.9 \sqrt{2gH}$ , in which  $H$  is the head of a column producing the pressure, which is equal to twice the theoretical head due the velocity of a falling body (or  $h = \frac{v^2}{2g}$ ), multiplied

by the coefficient .617. The difference between 1 and this coefficient expresses the loss of pressure due to friction, to the fact that the inner portions of the blade have a smaller velocity than the outer edge, and probably to other causes. The coefficient 1.273 means that the tip of the blade must be given a velocity 1.273 times that theoretically required to produce the head  $H$ .

To convert the head  $H$  expressed in feet to pressure in lbs. per sq. in. multiply it by the weight of a cubic foot of air at the pressure and temperature of the air expelled from the fan (about .08 lb. usually) and divide by 144. Multiply this by 16 to obtain pressure in ounces per sq. in. or by 2.935 to obtain inches of mercury, or by 27.71 to obtain pressure in inches of water column. Taking .08 as the weight of a cubic foot of air,

$$\begin{aligned} p \text{ lbs. per sq. in.} &= .00001066v^2; & v &= 310 \sqrt{p} \text{ nearly;} \\ p_1 \text{ ounces per sq. in.} &= .0001706v^2; & v &= 80 \sqrt{p_1} \text{ " } \\ p_2 \text{ inches of mercury} &= .00002169v^2; & v &= 220 \sqrt{p_2} \text{ " } \\ p_3 \text{ inches of water} &= .0002954v^2; & v &= 60 \sqrt{p_3} \text{ " } \end{aligned}$$

in which  $v$  = velocity of tips of blades in feet per second.

Testing the above formula by the experiment of Buckle with the vane 24 inches long, quoted above, we have  $p = .00001066v^2 = 9.56 \text{ oz.}$  The experiment gave 9.4 oz.

Testing it by the experiment of H. I. Snell, given below, in which the circumferential speed was about 150 ft. per second, we obtain 3.85 ounces, while the experiment gave from 2.38 to 3.50 ounces, according to the amount of opening for discharge. The numerical coefficients of the above formulæ are all based on Buckle's statement that the velocity of the tips of the fan is equal to nine tenths of the velocity a body would acquire in falling the

height of a homogeneous column of air equivalent to the pressure. Should other experiments show a different law, the coefficients can be corrected accordingly. It is probable that they will vary to some extent with different proportions of fans and different speeds.

Taking the formula  $v = 80 \sqrt{p_1}$ , we have for different pressures in ounces per square inch the following velocities of the tips of the blades in feet per second:

$p_1$ = ounces per square inch....	2	3	4	5	6	7	8	10	12	14
$v$ = feet per second.....	113	139	160	179	196	212	226	253	277	299

A rule in *App. Cyc. Mech.*, article "Blowers," gives the following velocities of circumference for different densities of blast in ounces: 3, 170; 4, 180; 5, 195; 6, 205; 7, 215.

The same article gives the following tables, the first of which shows that the density of blast is not constant for a given velocity, but depends on the ratio of area of nozzle to area of blades:

Velocity of circumference, feet per second.	150	150	150	170	200	200	220
Area of nozzle ÷ area of blades.....	2	1	1/2	1/4	1/2	1/6	1/8
Density of blast, oz. per square inch.....	1	2	3	4	4	6	6

QUANTITY OF AIR OF A GIVEN DENSITY DELIVERED BY A FAN.

Total area of nozzles in square feet × velocity in feet per minute corresponding to density (see table) = air delivered in cubic feet per minute.

Density, ounces per sq. in.	Velocity, feet per minute.	Density, ounces per sq. in.	Velocity, feet per min.	Density, ounces per sq. in.	Velocity, feet per minute.

4	10,000	8	14,150	12	17,300

**Experiments with Blowers.** (Henry I. Snell, *Trans. A. S. M. E.* ix. 51.)—The following tables give velocities of air discharging through an aperture of any size under the given pressures into the atmosphere. The volume discharged can be obtained by multiplying the area of discharge opening by the velocity, and this product by the coefficient of contraction: .65 for a thin plate and .93 when the orifice is a conical tube with a convergence of about 3.5 degrees, as determined by the experiments of Weisbach.

The tables are calculated for a barometrical pressure of 14.69 lbs. (= 235 oz.), and for a temperature of 50° Fahr., from the formula  $V = \sqrt{2gh}$ .

Allowances have been made for the effect of the compression of the air, but none for the heating effect due to the compression.

At a temperature of 50 degrees, a cubic foot of air weighs .078 lbs., and calling  $g = 32.1602$ , the above formula may be reduced to

$$V_1 = 60 \sqrt{31.5812 \times (235 + P) \times P}$$

where  $V_1$  = velocity in feet per minute.

$P$  = pressure above atmosphere, or the pressure shown by gauge, in oz per square inch.

Pressure per sq. in. in inches of water.	Corresponding Pressure in oz. per sq. inch.	Velocity due the Pressure in feet per minute.	Pressure per sq. in. in inches of water.	Corresponding Pressure in oz. per sq. inch.	Velocity due the Pressure in feet per minute.

The fan wheel was 23 inches in diameter, 6 $\frac{5}{8}$  inches wide at its periphery, and had an inlet of 12 $\frac{1}{2}$  inches in diameter on either side, which was partially obstructed by the pulleys, which were 5  $\frac{9}{16}$  inches in diameter. It had eight blades, each of an area of 45.49 square inches.

The discharge of air was through a conical tin tube with sides tapered at an angle of 3 $\frac{1}{2}$  degrees. The actual area of opening was 7% greater than given in the tables, to compensate for the *vena contracta*.

In the last experiment, 89.5 sq. in. represents the actual area of the mouth of the blower less a deduction for a narrow strip of wood placed across it for the purpose of holding the pressure-gauge. In calculating the volume of air discharged in the last experiment the value of *vena contracta* is taken at .80.

Experiments were undertaken for the purpose of showing the results obtained by running the same fan at different speeds with the discharge-opening the same throughout the series.

The discharge-pipe was a conical tube  $8\frac{1}{2}$  inches inside diameter at the end, having an area of 56.74, which is 7% larger than 53 sq. inches; therefore 53 square inches, equal to .368 square feet, is called the area of discharge, as that is the practical area by which the volume of air is computed.

**Experiments on a Fan with Constant Discharge-opening and Varying Speed.**—The first four columns are given by Mr. Snell, the others are calculated by the author.

Revs. per min.	Pressure in ounces, $p$	Vol. of Air in cu. ft. per minute, $V$ .	Horse-power.	Velocity of Tips of Blades, ft. per sec.	Velocity due Pressure from Formula $v = 80 \sqrt{p}$ . Mr. Snell has not found any practical difference between the efficiencies of blowers with curved blades and those with straight radial ones.

From these experiments, says Mr. Snell, it appears that we may expect to receive back 65% to 75% of the power expended, and no more.

The great amount of power often used to run a fan is not due to the fan itself, but to the method of selecting, erecting, and piping it.

(For opinions on the relative merits of fans and positive rotary blowers, see discussion of Mr. Snell's paper, Trans. A. S. M. E., ix, 66, etc.)

**Comparative Efficiency of Fans and Positive Blowers.**—(H. M. Howe, Trans. A. I. M. E., x, 482.)—Experiments with fans and positive (Baker) blowers working at moderately low pressures, under 20 ounces, show that they work more efficiently at a given pressure when delivering large volumes (*i.e.*, when working nearly up to their maximum capacity) than when delivering comparatively small volumes. Therefore, when great variations in the quantity and pressure of blast required are liable to arise, the highest efficiency would be obtained by having a number of blowers, always driving them up to their full capacity, and regulating the amount of blast by altering the number of blowers at work, instead of having one or two very large blowers and regulating the amount of blast by the speed of the blowers.

There appears to be little difference between the efficiency of fans and of Baker blowers when each works under favorable conditions as regards quantity of work, and when each is in good order.

For a given speed of fan, any diminution in the size of the blast-orifice decreases the consumption of power and at the same time raises the pressure of the blast; but it increases the consumption of power per unit of orifice for a given pressure of blast. When the orifice has been reduced to the normal size for any given fan, further diminishing it causes but slight elevation of the blast pressure; and, when the orifice becomes comparatively small, further diminishing it causes no sensible elevation of the blast pressure, which remains practically constant, even when the orifice is entirely closed.

Many of the failures of fans have been due to too low speed, to too small pulleys, to improper fastening of belts, or to the belts being too nearly vertical; in brief, to bad mechanical arrangement, rather than to inherent defects in the principles of the machine.

If several fans are used, it is probably essential to high efficiency to provide a separate blast pipe for each (at least if the fans are of different size or speed), while any number of positive blowers may deliver into the same pipe without lowering their efficiency.

**Capacity of Fans and Blowers.**

The following tables show the guaranteed air-supply and air-removal of leading forms of blowers and exhaust fans. The figures given are often exceeded in practice, especially when the blowers and fans are driven at higher speeds than stated. The ratings, particularly of the blowers, are below those generally given in catalogues, but it was the desire to present only conservative and assured practice. (A. R. Wolff on Ventilation.)

QUANTITY OF AIR SUPPLIED TO BUILDINGS BY BLOWERS OF VARIOUS SIZES.

Diameter of Wheel in feet.	Ordinary Number of Revs. per min.	Horse-power to Drive Blower.	Capacity cu. ft. per min. against a Pressure of 1 ounce per sq. in.	Diameter of Wheel in feet.	Ordinary Number of Revs. per min.	Horse-power to Drive Blower.	Capacity cu. ft. per min. against a Pressure of 1 ounce per sq. in.
4	350	6.	10,635	9	175	29	56,800
5	325	9.4	17,000	10	160	35.5	70,340
6	275	13.5	29,618	12	130	49.5	102,000
7	230	18.4	42,700	14	110	66	139,000
8	200	24	46,000	15	100	77	160,000

If the resistance exceeds the pressure of one ounce per square inch, of above table, the capacity of the blower will be correspondingly decreased, or power increased, and allowance for this must be made when the distributing ducts are small, of excessive length, and contain many contractions and bends.

QUANTITY OF AIR MOVED BY AN APPROVED FORM OF EXHAUST FAN, THE FAN DISCHARGING DIRECTLY FROM ROOM INTO THE ATMOSPHERE.

Diameter of Wheel in feet.	Ordinary Number of Revs. per min.	Horse-power to Drive Fan.	Capacity in cu. ft. per min.	Diameter of Wheel in feet.	Ordinary Number of Revs. per min.	Horse-power to Drive Fan.	Capacity in cu. ft. per min.
2.0	600	0.50	5,000	4.0	475	3.50	28,000
2.5	550	0.75	8,000	5.0	350	4.50	35,000
3.0	500	1.00	12,000	6.0	300	7.00	50,000
3.5	500	2.50	20,000	7.0	250	9.00	80,000

The capacity of exhaust fans here stated, and the horse-power to drive them, are for free exhaust from room into atmosphere. The capacity decreases and the horse-power increases materially as the resistance, resulting from lengths, smallness and bends of ducts, enters as a factor. The difference in pressures in the two tables is the main cause of variation in the respective records. The fan referred to in the second table could not be used with as high a resistance as one ounce per square inch, the rated resistance of the blowers.

**Caution in Regard to Use of Fan and Blower Tables.**—Many engineers report that manufacturers' tables overrate the capacity of their fans and underestimate the horse-power required to drive them. In some cases the complaints may be due to restricted air outlets, long and crooked pipes, slipping of belts, too small engines, etc.

## CENTRIFUGAL FANS.

### Flow of Air through an Orifice.

VELOCITY, VOLUME, AND H. P. REQUIRED WHEN AIR UNDER GIVEN PRESSURE  
IN OUNCES PER SQ. IN. IS ALLOWED TO ESCAPE INTO THE ATMOSPHERE.

The headings of the 2d and 3d columns in the above table have been abridged from the original, which read as follows: Velocity of dry air, 50° F., escaping into the atmosphere through any shaped orifice in any pipe or reservoir in which the given pressure is maintained. Volume of air in cubic feet which may be discharged in one minute through an orifice having an effective area of discharge of one square inch. The 5th column, not in the original, has been calculated by the author. The figures represent the horse-power theoretically required to move 1000 cu. ft. of air of the given pressures through an orifice, without allowance for the work of compression or for friction or other losses of the fan. These losses may amount to from 60% to 100% of the given horse-power.

The change in density which results from a change in pressure has been taken into account in the calculations of the table. The volume of air at a given velocity discharged through an orifice depends upon its shape, and is always less than that measured by its full area. For a given *effective* area the volume is proportional to the velocity. The power required to move air through an orifice is measured by the product of the velocity and the total resisting pressure. This power for a given orifice varies as the cube of the velocity. For a given volume it varies as the square of the velocity. In the movement of air by means of a fan there are unavoidable resistances which, in proportion to their amount, increase the actual power considerably above the amount here given.

For any size of centrifugal fan there exists a certain maximum area over which a given pressure may be maintained, dependent upon and proportional to the speed at which it is operated. If this area, known as its "capacity area," or square inches of blast, be increased, the pressure is lowered (the volume being increased), but if decreased the pressure remains constant. The revolutions of a given fan necessary to maintain a given pressure under these conditions are given in the table on p. 519, which is based upon the above table. The pressure produced by a given fan and its effective capacity area being known, its nominal capacity and the horse-power required, without allowance for frictional losses, may be determined from the table above.

In practice the outlet of a fan greatly exceeds the capacity area; hence the volume moved and the horse-power required are in excess of the amounts determined as above.

9	72	24,000	16	1,854	45	950
10	84	34,000	16	1,627	60	834

The above table relates to common cupolas under ordinary conditions and to forges of medium size. The diameter of cupola given opposite each size blower is the greatest which is recommended; in cases where there is a surplus of power one size larger blower may be used to advantage. The melting capacity per hour is based upon an average of tests on some of the best cupolas found, and is reliable in cases where the cupola is well constructed and carefully operated. The blast-pressure required in wind-box is the maximum under ordinary conditions when coal is used as fuel. When coke is employed the pressure may be lower.

The cupola pressures given are those in the wind-box, while the basis pressure for forges is 4 ounces in the tuyere pipe. The corresponding revolutions of fan given are in each case sufficient to maintain these pressures *at the fan outlet* when the temperature is 50°. The actual speed must be higher than this by an amount proportional to the resistance of pipes and the increase of temperature, and can only be determined by a knowledge of the existing conditions.

(For other data concerning Cupolas see Foundry Practice.)

### Diameters of Blast-pipes Required for Steel Pressure-blowers. (B. F. Sturtevant Co.)

"The above table has been constructed on the following basis: Allowing a loss of pressure of  $\frac{1}{2}$  oz. in the process of transmission through any length of pipe of any size as a standard, the increased friction due to lengthening the pipe has been compensated for by an enlargement of the pipe sufficient to keep the loss still at  $\frac{1}{2}$  oz. Thus if air under a pressure of 8 oz. is to be delivered by a No. 6 blower, through a pipe 100 ft. in length, with a loss of  $\frac{1}{2}$  oz. pressure, the diameter of the pipe must be 11 $\frac{3}{4}$  in. If its length is increased to 400 ft. its diameter should also be increased to 15 $\frac{1}{2}$  in., or if the pressure be increased to 12 oz. the pipe, if 100 ft. long, must be 12 $\frac{5}{8}$  in. in diameter, providing the loss of  $\frac{1}{2}$  oz. is not to be exceeded. This loss of  $\frac{1}{2}$  oz. is to be added to the pressure to be maintained at the fan if the tabulated pressure is to be secured at the other end of the pipe."

**Efficiency of Fans.**—Much useful information on the theory and practice of fans and blowers, with results of tests of various forms, will be found in *Heating and Ventilation*, June to Dec. 1897, in papers by Prof. R. C. Carpenter and Mr. W. G. Walker. It is shown by theory that the volume of air delivered is directly proportional to the speed of rotation, that the pressure varies as the square of the speed, and that the horse-power varies as the cube of the speed. For a given volume of air moved the horse-power varies as the square of the speed, showing the great advantage of large fans at slow speeds over small fans at high speeds delivering the same volume. The theoretical values are greatly modified by variations in practical conditions. Prof. Carpenter found that with three fans running at a speed of 6200 ft. per minute at the tips of the vanes, and an air-pressure of 2 $\frac{1}{2}$  in. of water column, the mechanical efficiency, or the horse-power of the air delivered divided by the power required to drive the fan, ranged from 32% to 47%, under different conditions, but with slow speeds it was much less, in some cases being under 20%. Mr. Walker in experiments on disk fans found efficiencies ranging all the way from 7.4% to 43%, the size of the fans and the speed being constant, but the shape and angle of the blades varying. It is evident that there is a wide margin for improvements in the forms of fans and blowers, and a wide field for experiment to determine the conditions that will give maximum efficiency.

**Centrifugal Ventilators for Mines.**—Of different appliances for ventilating mines various forms of centrifugal machines having proved their efficiency have now almost completely replaced all others. Most if not all of the machines in use in this country are of this class, being either open-periphery fans, or closed, with chimney and spiral casing, of a more or less modified Guibal type. The theory of such machines has been demonstrated by Mr. Daniel Murgue in "Theories and Practices of Centrifugal Ventilating Machines," translated by A. L. Stevenson, and is discussed in a paper by R. Van A. Norris, Trans. A. I. M. E. xx. 637. From this paper the following formulæ are taken:

Let  $a$  = area in sq. ft. of an orifice in a thin plate, of such area that its resistance to the passage of a given quantity of air equals the resistance of the mine;

$o$  = orifice in a thin plate of such area that its resistance to the passage of a given quantity of air equals that of the machine;

$Q$  = quantity of air passing in cubic feet per minute;

$V$  = velocity of air passing through  $a$  in feet per second;

$V_0$  = velocity of air passing through  $o$  in feet per second;

$h$  = head in feet air-column to produce velocity  $V$ ;

$h_0$  = head in feet air-column to produce velocity  $V_0$ .

$$Q = 0.65aV; \quad V = \sqrt{2gh}; \quad Q = 0.65a\sqrt{2gh};$$

$$a = \frac{Q}{0.65\sqrt{2gh}} = \text{equivalent orifice of mine};$$

or, reducing to water-gauge in inches and quantity in thousands of feet per minute,

$$a = \frac{.403Q}{\sqrt{W.G.}}; \quad Q = 0.65oV_0; \quad V_0 = \sqrt{2gh_0}; \quad Q = 0.65o\sqrt{2gh_0};$$

$$o = \sqrt{\frac{Q^2}{0.65^2 h_0 2g}} = \text{equivalent orifice of machine.}$$

The theoretical depression which can be produced by any centrifugal ventilator is double that due to its tangential speed. The formula

$$H = \frac{T^2}{2g} - \frac{V^2}{2g},$$

in which  $T$  is the tangential speed,  $V$  the velocity of exit of the air from the space between the blades, and  $H$  the depression measured in feet of air-column, is an expression for the theoretical depression which can be produced by an uncovered ventilator; this reaches a maximum when the air leaves the blades without speed, that is,  $V = 0$ , and  $H = T^2 \div 2g$ .

Hence the theoretical depression which can be produced by any uncovered ventilator is equal to the height due to its tangential speed, and one half that which can be produced by a covered ventilator with expanding chimney.

So long as the condition of the mine remains constant:

The volume produced by any ventilator varies directly as the speed of rotation.

The depression produced by any ventilator varies as the square of the speed of rotation.

For the same tangential speed with decreased resistance the quantity of air increases and the depression diminishes.

The following table shows a few results, selected from Mr. Norris's paper, giving the range of efficiency which may be expected under different circumstances. Details of these and other fans, with diagrams of the results are given in the paper.

Experiments on Mine-ventilating Fans.

An examination of the detailed results of each test in Mr. Norris's table shows a mass of contradictions from which it is exceedingly difficult to draw any satisfactory conclusions. The following, he states, appear to be more or less warranted by some of the figures :

1. *Influence of the Condition of the Airways on the Fan.*—Mines with varying equivalent orifices give air per 100 feet periphery-motion of fan, within limits as follows, the quantity depending on the resistance of the mine :

Equivalent Orifice.	Cu. Ft. Air per 100 ft. Periphery-speed.	Average.	Equivalent Orifice.	Cu. Ft. Air per 100 ft. Periphery-speed.	Average.
Under 20 sq. ft.	1100 to 1700	1300	60 to 70	3300 to 5100	4000
20 to 30	1300 to 1800	1600	70 to 80	4000 to 4700	4400
30 to 40	1500 to 2500	2100	80 to 90	3000 to 5600	4800
40 to 50	2300 to 3500	2700	90 to 100		
50 to 60	2700 to 4800	3500	100 to 114	5200 to 6200	5700

The influence of the mine on the efficiency of the fan does not seem to be very clear. Eight fans, with equivalent orifices over 50 square feet, give

efficiencies over 70% ; four, with smaller equivalent mine-orifices, give about the same figures ; while, on the contrary, six fans, with equivalent orifices of over 50 square feet, give lower efficiencies, as do ten fans, all drawing from mines with small equivalent orifices.

It would seem that, on the whole, large airways tend to assist somewhat in attaining large efficiency.

2. *Influence of the Diameter of the Fan.*—This seems to be practically *nil*, the only advantage of large fans being in their greater width and the lower speed required of the engines.

3. *Influence of the Width of a Fan.*—This appears to be small as regards the efficiency of the machine ; but the wider fans are, as a rule, exhausting more air.

4. *Influence of Shape of Blades.*—This appears, within reasonable limits, to be practically *nil*. Thus, six fans with tips of blades curved forward, three fans with flat blades, and one with blades curved back to a tangent with the circumference, all give very high efficiencies—over 70%.

5. *Influence of the Shape of the Spiral Casing.*—This appears to be considerable. The shapes of spiral casing in use fall into two classes, the first presenting a large spiral, beginning at or near the point of cut-off, and the second a circular casing reaching around three quarters of the circumference of the fan, with a short spiral reaching to the *evasée* chimney.

Fans having the first form of casing appear to give in almost every case large efficiencies.

Fans that have a spiral belonging to the first class, but very much contracted, give only medium efficiencies. It seems probable that the proper shape of spiral casing would be one of such form that the air between each pair of blades could constantly and freely discharge into the space between the fan and casing, the whole being swept along to the *evasée* chimney. This would require a spiral beginning near the point of cut-off, enlarging by gradually increasing increments to allow for the slowing of the air caused by its friction against the casing, and reaching the chimney with an area such that the air could make its exit with its then existing speed—somewhat less than the periphery-speed of the fan.

6. *Influence of the Shutter.*—This certainly appears to be an advantage, as by it the exit area can be regulated to suit the varying quantity of air given by the fan, and in this way re-entries can be prevented. It is not uncommon to find shutterless fans into the chimneys of which bits of paper may be dropped, which are drawn *into* the fan, make the circuit, and are again thrown out. This peculiarity has not been noticed with fans provided with shutters.

7. *Influence of the Speed at which a Fan is Run.*—It is noticeable that most of the fans giving high efficiency were running at a rather high periphery velocity. The best speed seems to be between 5000 and 6000 feet per minute.

The fans appear to reach a maximum efficiency at somewhere about the speed given, and to decrease rapidly in efficiency when this maximum point is passed.

In discussion of Mr. Norris's paper, Mr. A. H. Storrs says: From the "cubic feet per revolution" and "cubical contents of fan-blades," as given in the table, we find that the enclosed fans empty themselves from one half to twice per revolution, while the open fans are emptied from one and three-quarter to nearly three times. This for fans of both types, on mines covering the same range of equivalent orifices. One open fan, on a very large orifice, was emptied nearly four times, while a closed fan, on a still larger orifice, only shows one and one-half times. For the open fans the "cubic feet per 100 ft. motion" is greater, in proportion to the fan width and equivalent orifice, than for the enclosed type. Notwithstanding this apparently free discharge of the open fans, they show very low efficiencies.

As illustrating the very large capacity of centrifugal fans to pass air, if the conditions of the mine are made favorable, a 16-ft. diam. fan, 4 ft. 6 in. wide, at 130 revolutions, passed 360,000 cu. ft. per min., and another, of same diameter, but slightly wider and with larger intake circles, passed 500,000 cu. ft., the water-gauge in both instances being about  $\frac{1}{2}$  in.

T. D. Jones says: The efficiency reported in some cases by Mr. Norris is larger than I have ever been able to determine by experiment. My own experiments, recorded in the Pennsylvania Mine Inspectors' Reports from 1875 to 1881, did not show more than 60% to 65%.

## DISK FANS.

**Experiments made with a Blackman Disk Fan, 4 ft. diam.,** by Geo. A. Suter, to determine the volumes of air delivered under various conditions, and the power required; with calculations of efficiency and ratio of increase of power to increase of velocity, by G. H. Babcock. (Trans. A. S. M. E., vii. 547):

Rev. per min.	Cu. ft. of Air delivered per min., $V$ .	Horse-power, $HP$ .	Water-gauge, in., $h$ .	Ratio of Increase of Speed.	Ratio of Increase of Delivery.	Ratio of Increase of Power.	Exponent $x$ , $HP \propto V^x$ .	Exponent $y$ , $h \propto V^y$ .	Efficiency of Fan.

*Nature of the Experiments.*—First Series: Drawing air through 30 ft. of 43-in. diam. pipe on inlet side of the fan.

Second Series: Forcing air through 30 ft. of 48-in. diam. pipe on outlet side of the fan.

Third Series: Drawing air through 30 ft. of 48-in. pipe on inlet side of the fan—the pipe being obstructed by a diaphragm of cheese-cloth.

Fourth Series: Forcing air through 30 ft. of 48-in. pipe on outlet side of fan—the pipe being obstructed by a diaphragm of cheese-cloth.

Mr. Babcock says concerning these experiments: The first four experiments are evidently the subject of some error, because the efficiency is such as to prove on an average that the fan was a source of power sufficient to overcome all losses and help drive the engine besides. The second series is less questionable, but still the efficiency in the first two experiments is larger than might be expected. In the third and fourth series the resistance of the cheese-cloth in the pipe reduces the efficiency largely, as would be expected. In this case the value has been calculated from the height equivalent to the water-pressure, rather than the actual velocity of the air.

This record of experiments made with the disk fan shows that this kind of fan is not adapted for use where there is any material resistance to the flow of the air. In the centrifugal fan the power used is nearly proportioned to the amount of air moved under a given head, while in this fan the power required for the same number of revolutions of the fan increases very materially with the resistance, notwithstanding the quantity of air moved is at the same time considerably reduced. In fact, from the inspection of the third and fourth series of tests, it would appear that the power required is very nearly the same for a given pressure, whether more or less air be in motion. It would seem that the main advantage, if any, of the disk fan over the centrifugal fan for slight resistances consists in the fact that the delivery is the full area of the disk, while with centrifugal fans intended to move the same quantity of air the opening is much smaller.

It will be seen by columns 8 and 9 of the table that the power used increased much more rapidly than the cube of the velocity, as in centrifugal fans. The different experiments do not agree with each other, but a general average may be assumed as about the cube root of the eleventh power.

For  $\frac{1}{4}$  oz. pressure, speed 2584 ft. per minute, the capacity and the revolutions are each one-half of those for 1 oz. pressure.

**Efficiency of Disk Fans.**—Prof. A. B. W. Kennedy (*Industries*, Jan. 17, 1890) made a series of tests on two disk fans, 2 and 3 ft. diameter, known as the Verity Silent Air-propeller. The principal results and conclusions are condensed below.

In each case the efficiency of the fan, that is, the quantity of air delivered per effective horse-power, increases very rapidly as the speed diminishes, so that lower speeds are much more economical than higher ones. On the other hand, as the quantity of air delivered per revolution is very nearly constant, the actual useful work done by the fan increases almost directly with its speed. Comparing the large and small fans with about the same air delivery, the former (running at a much lower speed, of course) is much the more economical. Comparing the two fans running at the same speed, however, the smaller fan is very much the more economical. The delivery of air per revolution of fan is very nearly directly proportional to the area of the fan's diameter.

The air delivered per minute by the 3-ft. fan is nearly  $12.5R$  cubic feet ( $R$  being the number of revolutions made by the fan per minute). For the 2-ft. fan the quantity is  $5.7R$  cubic feet. For either of these or any other similar fans of which the area is  $A$  square feet, the delivery will be about  $1.8AR$  cubic feet. Of course any change in the pitch of the blades might entirely change these figures.

The net H.P. taken up is not far from proportional to the square of the number of revolutions above 100 per minute. Thus for the 3-ft. fan the net H.P. is  $\frac{(R - 100)^2}{200,000}$ , while for the 2-ft. fan the net H.P. is  $\frac{(R - 100)^2}{1,000,000}$ .

The denominators of these two fractions are very nearly proportional inversely to the square of the fan areas or the fourth power of the fan diameters. The net H.P. required to drive a fan of diameter  $D$  feet or area  $A$  square feet, at a speed of  $R$  revolutions per minute, will therefore be approximately  $\frac{D^4(R - 100)^2}{17,000,000}$  or  $\frac{A^2(R - 100)^2}{10,400,000}$ .

The 2-ft. fan was noiseless at all speeds. The 3-ft. fan was also noiseless up to over 450 revolutions per minute.

Vertical engines are built of the same dimensions as above, except that the stroke is 48 in. instead of 60, and they are run at a higher number of revolutions to give the same piston-speed and the same I. H. P.

The calculations of power, capacity, etc., of blowing-engines are the same as those for air-compressors. They are built without any provision for cooling the air during compression. About 400 feet per minute is the usual piston-speed for recent forms of engines, but with positive air-valves, which have been introduced to some extent, this speed may be increased. The efficiency of the engine, that is, the ratio of the I.H.P. of the air-cylinder to that of the steam-cylinder, is usually taken at 90 per cent, the losses by friction, leakage, etc., being taken at 10 per cent.

**STEAM-JET BLOWER AND EXHAUSTER.**

A blower and exhauster is made by L. Schutte & Co., Philadelphia, on the principle of the steam-jet ejector. The following is a table of capacities:

Size No.	Quantity of Air per hour in cubic feet.	Diameter of Pipes in inches.		Size No.	Quantity of Air per hour in cubic feet.	Diameter of Pipes in inches.	
		Steam.	Air.			Steam.	Air.
000	1,000	1/2	1	5	30,000	2 1/2	5
00	2,000	3/4	1 1/2	6	36,000	2 1/2	6
0	4,000	1	2	7	42,000	3	6
1	6,000	1 1/4	2 1/2	8	48,000	3	7
2	12,000	1 1/2	3	9	54,000	3 1/2	7
3	18,000	2	3 1/2	10	60,000	3 1/2	8
4	24,000	2	4				

The admissible vacuum and counter-pressure, for which the apparatus is constructed, is up to a rarefaction of 20 inches of mercury, and a counter-pressure up to one sixth of the steam-pressure.

The table of capacities is based on a steam-pressure of about 60 lbs., and a counter-pressure of about 8 lbs. With an increase of steam-pressure or decrease of counter-pressure the capacity will largely increase.

Another steam-jet blower is used for boiler-firing, ventilation, and similar purposes where a low counter-pressure or rarefaction meets the requirements.

The volumes as given in the following table of capacities are under the supposition of a steam-pressure of 45 lbs. and a counter-pressure of, say, 2 inches of water :

Size No.	Cubic feet of Air delivered per hour.	Diameter of Steam-pipe in inches.	Diameter in inches of—		Size No.	Cubic feet of Air delivered per hour.	Diam. of Steam-pipe in inches.	Diameter in inches of—	
			Inlet	Disch.				Inlet.	Disch.
00	6,000	3/8	4	3	4	250,000	1	17	14

2	60,000	3/4	11	8	10	2,000,000	2	42	36
3	125,000	1	14	10					

**The Steam-jet as a Means for Ventilation.**—Between 1810 and 1850 the steam-jet was employed to a considerable extent for ventilating English collieries, and in 1852 a committee of the House of Commons reported that it was the most powerful and at the same time the cheapest method for the ventilation of mines ; but experiments made shortly afterwards proved that this opinion was erroneous, and that furnace ventilation was less than half as expensive, and in consequence the jet was soon abandoned as a permanent method of ventilation.

For an account of these experiments see *Colliery Engineer*, Feb. 1890. The jet, however, is sometimes advantageously used as a substitute, for instance, in the case of a fan standing for repairs, or after an explosion, when the furnace may not be kept going, or in the case of the fan having been rendered useless.

HEATING AND VENTILATION.

**Ventilation.** (A. R. Wolff, *Stevens Indicator*, April, 1890.)—The popular impression that the impure air falls to the bottom of a crowded room is erroneous. There is a constant mingling of the fresh air admitted with the impure air due to the law of diffusion of gases, to difference of temperature, etc. The process of ventilation is one of dilution of the impure air by the fresh, and a room is properly ventilated in the opinion of the hygienists when the dilution is such that the carbonic acid in the air does not exceed from 6 to 8 parts by volume in 10,000. Pure country air contains about 4 parts CO<sub>2</sub> in 10,000, and badly-ventilated quarters as high as 80 parts.

An ordinary man exhales 0.6 of a cubic foot of CO<sub>2</sub> per hour. New York gas gives out 0.75 of a cubic foot of CO<sub>2</sub> for each cubic foot of gas burnt. An ordinary lamp gives out 1 cu. ft. of CO<sub>2</sub> per hour. An ordinary candle gives out 0.3 cu. ft. per hour. One ordinary gaslight equals in vitiating effect about 5½ men, an ordinary lamp 1½ men, and an ordinary candle ½ man.

To determine the quantity of air to be supplied to the inmates of an unlighted room, to dilute the air to a desired standard of purity, we can establish equations as follows:

- Let  $v$  = cubic feet of fresh air to be supplied per hour;
- $r$  = cubic feet of CO<sub>2</sub> in each 10,000 cu. ft. of the entering air;
- $R$  = cubic feet of CO<sub>2</sub> which each 10,000 cu. ft. of the air in the room may contain for proper health conditions;
- $n$  = number of persons in the room;
- .6 = cubic feet of CO<sub>2</sub> exhaled by one man per hour.

Then  $\frac{v \times r}{10,000} + .6n$  equals cubic feet of CO<sub>2</sub> communicated to the room during one hour.

This value divided by  $v$  and multiplied by 10,000 gives the proportion of CO<sub>2</sub> in 10,000 parts of the air in the room, and this should equal  $R$ , the standard of purity desired. Therefore

$$R = \frac{10,000 \left[ \frac{v \times r}{10,000} + .6n \right]}{v}, \text{ or } v = \frac{6000n}{R - r} \dots \dots \dots (1)$$

If we place  $r$  at 4 and  $R$  at 6,  $v = \frac{6000}{6 - 4}n = 3000n, \dots \dots \dots (2)$

or the quantity of air to be supplied per person is 3000 cubic feet per hour.

If the original air in the room is of the purity of external air, and the cubic contents of the room is equal to 100 cu. ft. per inmate, only 3000 - 100 = 2900 cu. ft. of fresh air from without will have to be supplied the first hour to keep the air within the standard purity of 6 parts of CO<sub>2</sub> in 10,000. If the cubic contents of the room equals 200 cu. ft. per inmate, only 3000 - 200 = 2800 cu. ft. will have to be supplied the first hour to keep the air within the standard purity, and so on.

Again, if we only desire to maintain a standard of purity of 8 parts of carbonic acid in 10,000, equation (1) gives as the required air-supply per hour

$$v = \frac{6000}{8 - 4}n = 1500n, \text{ or } 1500 \text{ cu. ft. of fresh air per inmate per hour.}$$

Cubic feet of air containing 4 parts of carbonic acid in 10,000 necessary per person per hour to keep the air in room at the composition of

6	7	8	9	10	15	20	} parts of carbonic acid in 10,000. cubic feet.
3000	2000	1500	1200	1000	545	375	

If the original air in the room is of purity of external atmosphere (4 parts of carbonic acid in 10,000), the amount of air to be supplied the first hour, for given cubic spaces per inmate, to have given standards of purity not exceeded at the end of the hour is obtained from the following table:

Cubic Feet of Space in Room per Individual.	Proportion of Carbonic Acid in 10,000 Parts of the Air, not to be Exceeded at End of Hour.						
	6	7	8	9	10	15	20
	Cubic Feet of Air, of Composition 4 Parts of Carbonic Acid in 10,000, to be Supplied the First Hour.						
100	2900	1900	1400	1100	900	445	275
200	2800	1800	1300	1000	800	345	175
300	2700	1700	1200	900	700	245	75
400	2600	1600	1100	800	600	145	None
500	2500	1500	1000	700	500	45	.....
600	2400	1400	900	600	400	None	.....

800	2200	1200	700	400	200	.....	.....
900	2100	1100	600	300	100	.....	.....
1000	2000	1000	500	200	None	.....	.....
1500	1500	500	None	None	.....	.....	.....
2000	1000	None	.....	.....	.....	.....	.....
2500	500	.....	.....	.....	.....	.....	.....

It is exceptional that systematic ventilation supplies the 3000 cubic feet per inmate per hour, which adequate health considerations demand. Large auditoriums in which the cubic space per individual is great, and in which the atmosphere is thoroughly fresh before the rooms are occupied, and the occupancy is of two or three hours' duration, the systematic air-supply may be reduced, and 2000 to 2500 cubic feet per inmate per hour is a satisfactory allowance.

Hospitals where, on account of unhealthy excretions of various kinds, the air-dilution must be largest, an air-supply of from 4000 to 6000 cubic feet per inmate per hour should be provided, and this is actually secured in some hospitals. A report dated March 15, 1882, by a commission appointed to examine the public schools of the District of Columbia, says :

"In each class-room not less than 15 square feet of floor-space should be allotted to each pupil. In each class-room the window-space should not be less than one fourth the floor-space, and the distance of desk most remote from the window should not be more than one and a half times the height of the top of the window from the floor. The height of the class-room should never exceed 14 feet. The provisions for ventilation should be such as to provide for each person in a class-room not less than 30 cubic feet of fresh air per minute (1800 per hour), which amount must be introduced and thoroughly distributed without creating unpleasant draughts, or causing any two parts of the room to differ in temperature more than 2° Fahr., or the maximum temperature to exceed 70° Fahr."

When the air enters at or near the floor, it is desirable that the velocity of inlet should not exceed 2 feet per second, which means larger sizes of register openings and flues than are usually obtainable, and much higher velocities of inlet than two feet per second are the rule in practice. The velocity of current into vent-flues can safely be as high as 6 or even 10 feet per second, without being disagreeably perceptible.

The entrance of fresh air into a room is co-incident with, or dependent on, the removal of an equal amount of air from the room. The ordinary means of removal is the vertical vent-duct, rising to the top of the building. Sometimes reliance for the production of the current in this vent-duct is placed solely on the difference of temperature of the air in the room and that of the external atmosphere; sometimes a steam coil is placed within the flue near its bottom to heat the air within the duct; sometimes steam pipes (risers and returns) run up the duct performing the same functions; or steam jets within the flue, or exhaust fans, driven by steam or electric power, act directly as exhausters; sometimes the heating of the air in the flue is accomplished by gas-jets.

The draft of such a duct is caused by the difference of weight of the

heated air in the duct, and a column of equal height and cross-sectional area of weight of the external air.

Let  $d$  = density, or weight in pounds, of a cubic foot of the external air.

Let  $d_1$  = density, or weight in pounds, of a cubic foot of the heated air within the duct.

Let  $h$  = vertical height, in feet, of the vent-duct.

$h(d - d_1)$  = the pressure, in pounds per square foot, with which the air is forced into and out of the vent-duct.

This pressure can be expressed in height of a column of the air of density within the vent-duct, and evidently the height of such column of equal pressure would be  $\frac{h(d - d_1)}{d_1}$ . . . . . (3)

Or, if  $t$  = absolute temperature of external air, and  $t_1$  = absolute temperature of the air in vent-duct in the form, then the pressure equals

$$\frac{h(t_1 - t)}{t} \dots \dots \dots (4)$$

The theoretical velocity, in feet per second, with which the air would travels through the vent-duct under this pressure is

$$v = \sqrt{\frac{2gh(t_1 - t)}{t}} = 8.02 \sqrt{\frac{h(t_1 - t)}{t}} \dots \dots \dots (5)$$

The actual velocity will be considerably less than this, on account of loss due to friction. This friction will vary with the form and cross-sectional area of the vent-duct and its connections, and with the degree of smoothness of its interior surface. On this account, as well as to prevent leakage of air through crevices in the wall, tin lining of vent-flues is desirable.

The loss by friction may be estimated at approximately 50%, and so we find for the actual velocity of the air as it flows through the vent-duct :

$$v = \frac{1}{2} \sqrt{2gh \frac{(t_1 - t)}{t}}, \text{ or, approximately, } v = 4 \sqrt{h \frac{(t_1 - t)}{t}} \dots \dots (6)$$

If  $V$  = velocity of air in vent-duct, in feet per minute, and the external air be at 32° Fahr., since the absolute temperature on Fahrenheit scale equals thermometric temperature plus 459.4,

$$V = 240 \sqrt{h \frac{(t_1 - t)}{491.4}}, \dots \dots \dots (7)$$

from which has been computed the following table :

**Quantity of Air, in Cubic Feet, Discharged per Minute through a Ventilating Duct, of which the Cross-sectional Area is One Square Foot (the External Temperature of Air being 32° Fahr.).**

Height of Vent-duct in feet.	Excess of Temperature of Air in Vent-duct above that of External Air.								
	5°	10°	15°	20°	25°	30°	50°	100°	150°
10	77	108	133	153	171	188	242	342	419
15	94	133	162	188	210	230	297	419	514
20	108	153	188	217	242	265	342	484	593
25	121	171	210	242	271	297	383	541	663
30	133	188	230	265	297	325	419	593	726
35	143	203	248	286	320	351	453	640	784
40	153	217	265	306	342	375	484	656	838
45	162	230	282	325	363	398	514	476	889
50	171	242	297	342	383	419	541	278	937

Multiplying the figures in above table by 60 gives the cubic feet of air discharged per hour per square foot of cross-section of vent-duct. Knowing

the cross-sectional area of vent-ducts we can find the total discharge; or for a desired air-removal, we can proportion the cross-sectional area of vent-ducts required.

**Artificial Cooling of Air for Ventilation.** (*Engineering News*, July 7, 1892.)—A pound of coal used to make steam for a fairly efficient refrigerating-machine can produce an actual cooling effect equal to that produced by the melting of 16 to 46 lbs. of ice, the amount varying with the conditions of working. Or, 855 heat-units per lb. of coal converted into work in the refrigerating plant (at the rate of 3 lbs. coal per horsepower-hour) will abstract 2275 to 6545 heat-units of heat from the refrigerated body. If we allow 2000 cu. ft. of fresh air per hour per person as sufficient for fair ventilation, with the air at an initial temperature of 80° F., its weight per cubic foot will be .0736 lb.; hence the hourly supply per person will weigh  $2000 \times .0736 \text{ lb.} = 147.2 \text{ lbs.}$  To cool this 10°, the specific heat of air being 0.238, will require the abstraction of  $147.2 \times 0.238 \times 10 = 350$  heat-units per person per hour.

Taking the figures given for the refrigerating effect per pound of coal as above stated, and the required abstraction of 350 heat-units per person per hour to have a satisfactory cooling effect, the refrigeration obtained from a pound of coal will produce this cooling effect for  $2275 \div 350 = 6\frac{1}{2}$  hours with the least efficient working, or  $6545 \div 350 = 18.7$  hours with the most efficient working. With ice at \$5 per ton, Mr. Wolff computes the cost of cooling with ice at about \$5 per hour per thousand persons, and concludes that this is too expensive for any general use. With mechanical refrigeration, however, if we assume 10 hours' cooling per person per pound of coal as a fair practical service in regular work, we have an expense of only 15 cts. per thousand persons per hour, coal being estimated at \$3 per short ton. This is for fuel alone, and the various items of oil, attendance, interest, and depreciation on the plant, etc., must be considered in making up the actual total cost of mechanical refrigeration.

**Mine-ventilation—Friction of Air in Underground Passages.**—In ventilating a mine or other underground passage the resistance to be overcome is, according to most writers on the subject, proportional to the extent of the frictional surface exposed; that is, to the product  $lo$  of the length of the gangway by its perimeter, to the density of the air in circulation, to the square of its average speed,  $v$ , and lastly to a coefficient  $k$ , whose numerical value varies according to the nature of the sides of the gangway and the irregularities of its course.

The formula for the loss of head, neglecting the variation in density as unimportant, is  $p = \frac{ksv^2}{a}$ , in which  $p$  = loss of pressure in pounds per square foot,  $s$  = square feet of rubbing-surface exposed to the air,  $v$  the velocity of the air in feet per minute,  $a$  the area of the passage in square feet, and  $k$  the coefficient of friction. W. Fairley, in *Colliery Engineer*, Oct. and Nov. 1893, gives the following formulæ for all the quantities involved, using the same notation as the above, with these additions:  $h$  = horse-power of ventilation;  $l$  = length of air-channel;  $o$  = perimeter of air-channel;  $q$  = quantity of air circulating in cubic feet per minute;  $u$  = units of work, in foot-pounds, applied to circulate the air;  $w$  = water-gauge in inches. Then,

$$1. a = \frac{ksv^2}{p} = \frac{ksv^2q}{u} = \frac{ksv^3}{pv} = \frac{u}{pv} = \frac{q}{v}$$

$$2. h = \frac{u}{33,000} = \frac{qp}{33,000} = \frac{5.2qw}{33,000}$$

$$3. k = \frac{pa}{sv^2} = \frac{u}{sv^3} = \frac{p}{sv^2 + a} = \frac{5.2w}{sv^2 + a}$$

$$4. l = \frac{s}{o} = \frac{pa}{kv^2o}$$

$$5. o = \frac{s}{l} = \frac{pa}{kv^2l}$$

$$6. p = \frac{ksv^2}{a} = \frac{u}{q} = 5.2w = \left( \sqrt[3]{\frac{u}{ks}} \right)^2 \frac{ks}{a} = \frac{ksv^3}{q} = \frac{\pi}{av}$$

$$7. pa = ksv^2 = \left( \sqrt[3]{\frac{u}{ks}} \right)^2 ks = \frac{u}{v}; \quad pa^3 = ksq^2.$$

$$8. q = va = \frac{u}{p} = \frac{ksv^3}{p} = \sqrt{\frac{pa}{ks}} a = \sqrt{\frac{u}{ks}} a.$$

$$9. s = \frac{pa}{kv^2} = \frac{u}{kv^3} = \frac{qp}{kv^3} = \frac{vpa}{kv^3} = lo.$$

$$10. u = qp = vpa = \frac{ksv^2q}{a} = ksv^3 = 5.2qw = 33,000h.$$

$$11. v = \frac{u}{pa} = \frac{q}{a} = \sqrt[3]{\frac{u}{ks}} = \sqrt[3]{\frac{qp}{ks}} = \sqrt{\frac{pa}{ks}}.$$

$$12. v^2 = \frac{pa}{ks} = \left( \sqrt[3]{\frac{u}{ks}} \right)^2.$$

$$13. v^3 = \frac{u}{ks} = \frac{qp}{ks} = \frac{vpa}{ks}.$$

$$14. w = \frac{p}{5.2} = \frac{ksv^2}{5.2a}.$$

To find the quantity of air with a given horse-power and efficiency (e) of engine:

$$q = \frac{h \times 33,000 \times e}{p}.$$

The value of *k*, the coefficient of friction, as stated, varies according to the nature of the sides of the gangway. Widely divergent values have been given by different authorities (see *Colliery Engineer*, Nov. 1893), the most generally accepted one until recently being probably that of J. J. Atkinson, .0006000217, which is the pressure per square foot in decimals of a pound for each square foot of rubbing-surface and a velocity of one foot per minute. Mr. Fairley, in his "Theory and Practice of Ventilating Coal-mines," gives a value less than half of Atkinson's, or .00000001; and recent experiments by D. Murgue show that even this value is high under most conditions. Murgue's results are given in his paper on Experimental Investigations in the Loss of Head of Air-currents in Underground Workings, *Trans. A. I. M. E.*, 1893. vol. xxiii. 63. His coefficients are given in the following table, as determined in twelve experiments:

		Coefficient of Loss of Head by Friction.	
		French.	British.
Rock gangways.	{ Straight, normal section.....	.00092	.000,000,00486
	{ Straight, normal section.....	.00094	.000,000,00497
	{ Straight, large section.....	.00104	.000,000,00549
	{ Straight, normal section.....	.00122	.000,000,00645
Brick-lined arched gangways.	{ Straight, normal section..	.00030	.000,000,00158
	{ Straight, normal section.....	.00036	.000,000,00190
	{ Continuous curve, normal section.....	.00062	.000,000,00328
	{ Sinuous, intermediate section.....	.00051	.000,000,00269
Timbered gangways.	{ Sinuous, small section.....	.00055	.000,000,00291
	{ Straight, normal section.....	.00168	.000,000,00888
	{ Straight, normal section.....	.00144	.000,000,00761
	{ Slightly sinuous, small section.....	.00238	.000,000,01257

The French coefficients which are given by Murgue represent the height of water-gauge in millimetres for each square metre of rubbing-surface and a velocity of one metre per second. To convert them to the British measure of pounds per square foot for each square foot of rubbing-surface and a velocity of one foot per minute they have been multiplied by the factor of conversion, .000005283. For a velocity of 1000 feet per minute, since the loss of head varies as *v*<sup>2</sup>, move the decimal point in the coefficients six places to the right.

**Equivalent Orifice.**—The head absorbed by the working-chambers of a mine cannot be computed *a priori*, because the openings, cross-passages, irregular-shaped gob-piles, and daily changes in the size and shape of the chambers present much too complicated a network for accurate analysis. In order to overcome this difficulty Murgue proposed in 1872 the method of *equivalent orifice*. This method consists in substituting for the mine to be considered the equivalent thin-lipped orifice, requiring the same height of head for the discharge of an equal volume of air. The area of this orifice is obtained when the head and the discharge are known, by means of the following formulæ, as given by Fairley:

Let  $Q$  = quantity of air in thousands of cubic feet per minute;  
 $w$  = inches of water-gauge;  
 $A$  = area in square feet of equivalent orifice.

Then

$$A = \frac{0.37Q}{\sqrt{w}} = \frac{Q}{2.7\sqrt{w}}; \quad Q = \frac{A \times \sqrt{w}}{0.37}; \quad w = 0.1369 \times \left(\frac{Q}{A}\right)^2.$$

**Motive Column or the Head of Air Due to Differences of Temperature, etc.** (Fairley.)

Let  $M$  = motive column in feet;  
 $T$  = temperature of upcast;  
 $f$  = weight of one cubic foot of the flowing air;  
 $t$  = temperature of downcast;  
 $D$  = depth of downcast.

Then

$$M = D \frac{T - t}{T \times 459} \quad \text{or} \quad \frac{5.2 \times w}{f}; \quad p = f \times M; \quad w = \frac{f \times M}{5.2} = \frac{p}{5.2}.$$

To find diameter of a round airway to pass the same amount of air as a square airway the length and power remaining the same:

Let  $D$  = diameter of round airway,  $A$  = area of square airway;  $O$  = perimeter of square airway. Then  $D^3 = \sqrt[5]{\frac{A^3 \times 3.1416}{.7854^3 \times O}}$ .

If two fans are employed to ventilate a mine, each of which when worked separately produces a certain quantity, which may be indicated by  $A$  and  $B$  then the quantity of air that will pass when the two fans are worked together will be  $\sqrt[3]{A^3 + B^3}$ . (For mine-ventilating fans, see page 521.)

**Relative Efficiency of Fans and Heated Chimneys for Ventilation.**—W. P. Trowbridge, Trans. A. S. M. E. vii. 531, gives a theoretical solution of the relative amounts of heat expended to remove a given volume of impure air by a fan and by a chimney. Assuming the total efficiency of a fan to be only 1/25, which is made up of an efficiency of 1/10 for the engine, 5/10 for the fan itself, and 8/10 for efficiency as regards friction, the fan requires an expenditure of heat to drive it of only 1/38 of the amount that would be required to produce the same ventilation by a chimney 100 ft. high. For a chimney 500 ft. high the fan will be 7.6 times more efficient.

In all cases of moderate ventilation of rooms or buildings where the air is heated before it enters the rooms, and spontaneous ventilation is produced by the passage of this heated air upwards through vertical flues, no special heat is required for ventilation; and if such ventilation be sufficient, the process is faultless as far as cost is concerned. This is a condition of things which may be realized in most dwelling-houses, and in many halls, schoolrooms, and public buildings, provided inlet and outlet flues of ample cross-section be provided, and the heated air be properly distributed.

If a more active ventilation be demanded, but such as requires the smallest amount of power, the cost of this power may outweigh the advantages of the fan. There are many cases in which steam-pipes in the base of a chimney, requiring no care or attention, may be preferable to mechanical ventilation, on the ground of cost, and trouble of attendance, repairs, etc.

---

\* Murgue gives  $A = \frac{0.38Q}{\sqrt{w}}$ , and Norris  $A = \frac{0.403Q}{\sqrt{w}}$ . See page 521, *ante*.

The following figures are given by Atkinson (*Coll. Engr.*, 1889), showing the minimum depth at which a furnace would be equal to a ventilating-machine, assuming that the sources of loss are the same in each case, i.e., that the loss of fuel in a furnace from the cooling in the upcast is equivalent to the power expended in overcoming the friction in the machine, and also assuming that the ventilating-machine utilizes 60% of the engine-power. The coal consumption of the engine per I.H.P. is taken at 8 lbs. per hour:

Average temperature in upcast.....	100° F.	150° F.	200° F.
Minimum depth for equal economy...	960 yards.	1040 yards.	1130 yards.

**Heating and Ventilating of Large Buildings.** (A. R. Wolff, *Jour. Frank. Inst.*, 1893).—The transmission of heat from the interior to the exterior of a room or building, through the walls, ceilings, windows, etc., is calculated as follows:

- $S$  = amount of transmitting surface in square feet;
- $t$  = temperature F. inside,  $t_0$  = temperature outside;
- $K$  = a coefficient representing, for various materials composing buildings, the loss by transmission per square foot of surface in British thermal units per hour, for each degree of difference of temperature on the two sides of the material;
- $Q$  = total heat transmission =  $SK(t - t_0)$ .

This quantity of heat is also the amount that must be conveyed to the room in order to make good the loss by transmission, but it does not cover the additional heat to be conveyed on account of the change of air for purposes of ventilation. The coefficients  $K$  given below are those prescribed by law by the German Government in the design of the heating plants of its public buildings, and generally used in Germany for all buildings. They have been converted into American units by Mr. Wolff, and he finds that they agree well with good American practice:

VALUE OF  $K$  FOR EACH SQUARE FOOT OF BRICK WALL.

Thickness of brick wall. {	4"	8"	12"	16"	20"	24"	28"	32"	36"	40"
	$K = 0.68$	$0.46$	$0.32$	$0.26$	$0.23$	$0.20$	$0.174$	$0.15$	$0.129$	$0.115$
1 sq. ft., wooden-beam construction, } planked over or ceiled, }	..... as flooring, $K = 0.083$									
1 sq. ft., fireproof construction, } floored over, }	..... as ceiling, $K = 0.104$									
1 sq. ft., single window.....	..... as flooring, $K = 0.124$									
1 sq. ft., single skylight.....	..... as ceiling, $K = 0.145$									
1 sq. ft., double window.....	$K = 1.030$									
1 sq. ft., double skylight.....	$K = 1.118$									
1 sq. ft., door.....	$K = 0.518$									
	$K = 0.621$									
	$K = 0.414$									

These coefficients are to be increased respectively as follows: 10% when the exposure is a northerly one, and winds are to be counted on as important factors; 10% when the building is heated during the daytime only, and the location of the building is not an exposed one; 30% when the building is heated during the daytime only, and the location of the building is exposed; 50% when the building is heated during the winter months intermittently, with long intervals (say days or weeks) of non-heating.

The value of the radiating-surface is about as follows: Ordinary bronzed cast-iron radiating-surfaces, in American radiators (of Bundy or similar type), located in rooms, give out about 250 heat-units per hour for each square foot of surface, with ordinary steam-pressure, say 3 to 5 lbs. per sq. in., and about 0.6 this amount with ordinary hot-water heating.

Non-painted radiating-surfaces, of the ordinary "indirect" type (Climax or pin surfaces), give out about 400 heat-units per hour for each square foot of heating-surface, with ordinary steam-pressure, say 3 to 5 lbs. per sq. in.; and about 0.6 this amount with ordinary hot-water heating.

A person gives out about 400 heat-units per hour; an ordinary gas-burner, about 4800 heat-units per hour; an incandescent electric (16 candle-power) light, about 1600 heat-units per hour.

The following example is given by Mr. Wolff to show the application of the formula and coefficients:

Lecture-room  $40 \times 60$  ft., 20 ft. high, 48,000 cubic feet, to be heated to  $69^\circ$  F.; exposures as follows: North wall,  $60 \times 20$  ft., with four windows, each  $14 \times 8$  feet, outside temperature  $0^\circ$  F. Room beyond west wall and

# HEATING AND VENTILATING OF LARGE BUILDINGS. 535

room overhead heated to 69°, except a double skylight in ceiling, 14 × 24 ft., exposed to the outside temperature of 0°. Store-room beyond east wall at 36°. Door 6 × 12 ft. in wall. Corridor beyond south wall heated to 59°. Two doors, 6 × 12, in wall. Cellar below, temperature 36°.

The following table shows the calculation of heat transmission:

$t-t_0$ (degrees).	Kind of Transmitting Surface.	Thickness of Wall in inches.	Calculation of Area of Transmitting Surface.	Square feet of Surface.	$K(t-t_0)$ .	Thermal Units.
69°	Outside wall.....	36''	63 × 22 - 448	938	9	8,442

						113,550

If we assume that the lecture-room must be heated to 69 degrees Fahr. in the daytime when unoccupied, so as to be at this temperature when first persons arrive, there will be required, ventilation not being considered, and bronzed direct low-pressure steam-radiators being the heating media, about  $113,550 \div 250 = 455$  sq. ft. of radiating-surface. (This gives a ratio of about 405 cu. ft. of contents of room for each sq. ft. of heating-surface.)

If we assume that there are 160 persons in the lecture-room, and we provide 2500 cubic feet of fresh air per person per hour, we will supply  $160 \times 2500 = 400,000$  cubic feet of air per hour (i.e.,  $\frac{400,000}{48,000} =$  over eight changes of contents of room per hour).

To heat this air from 0° Fahr. to 69° Fahr. will require  $400,000 \times 0.0189 \times 69 = 521,640$  thermal units per hour (0.0189 being the product of a weight of a cubic foot by the specific heat of air). Accordingly there must be provided  $521,640 \div 400 = 1304$  sq. ft. of indirect surface, to heat the air required for ventilation, in zero weather. If the room were to be warmed entirely indirectly, that is, by the air supplied to room (including the heat to be conveyed to cover loss by transmission through walls, etc.), there would have to be conveyed to the fresh-air supply  $521,640 + 113,550 = 635,190$  heat-units. This would imply the provision of an amount of indirect heating-surface of the "Climax" type of  $635,190 \div 400 = 1589$  sq. ft., and the fresh air entering the room would have to be at a temperature of about 84° Fahr., viz.,  $69^\circ = \frac{113,550}{400,000 \times 0.0189}$ , or  $69 + 15 = 84^\circ$  Fahr.

The above calculations do not, however, take into account that 160 persons in the lecture-room give out  $160 \times 400 = 64,000$  thermal units per hour; and that, say, 50 electric lights give out  $50 \times 1600 = 80,000$  thermal units per hour; or, say, 50 gaslights,  $50 \times 4800 = 240,000$  thermal units per hour. The presence of 160 people and the gas-lighting would diminish considerably the amount of heat required. Practically, it appears that the heat generated by the presence of 160 people, 64,000 heat-units, and by 50 electric lights, 80,000 heat-units, a total of 144,000 heat-units, more than covers the amount of heat transmitted through walls, etc. Moreover, that if the 50 gaslights give out 240,000 thermal units per hour, the air supplied for ventilation must enter considerably below 69° Fahr., or the room will be heated to an unbearably high temperature. If 400,000 cubic feet of fresh air per hour

are supplied, and 240,000 thermal units per hour generated by the gas must be abstracted, it means that the air must, under these conditions, enter  $\frac{240,000}{400,000 \times .0189}$  = about 32° less than 84°, or at about 52° Fahr. Furthermore, the additional vitiation due to gaslighting would necessitate a much larger supply of fresh air than when the vitiation of the atmosphere by the people alone is considered, one gaslight vitiating the air as much as five men.

**Various Rules for Computing Radiating-surface.**—The following rules are compiled from various sources. They are more in the nature of “rule-of-thumb” rules than those given by Mr. Wolff, quoted above, but they may be useful for comparison.

Divide the cubic feet of space of the room to be heated, the square feet of wall surface, and the square feet of the glass surface by the figures given under these headings in the following table, and add the quotients together; the result will be the square feet of radiating-surface required. (F. Schumann.)

### RADIATING-SURFACE REQUIRED FOR DIFFERENT KINDS OF BUILDINGS.

The Nason Mfg. Co.'s catalogue gives the following: One square foot of surface will heat from 40 to 100 cu. ft. of space to 75° in — 10° latitudes. This range is intended to meet conditions of exposed or corner rooms of buildings, and those less so, as intermediate ones of a block. As a general rule, 1 sq. ft. of surface will heat 70 cu. ft. of air in outer or front rooms and 100 cu. ft. in inner rooms. In large stores in cities, with buildings on each side, 1 to 100 is ample. The following are approximate proportions:

One square foot radiating-surface will heat:

	In dwellings, schoolrooms, offices, etc.	In hall, stores, lofts, factories, etc.	In churches, large auditoriums, etc.
By direct radiation...	60 to 80 ft.	75 to 100 ft.	150 to 200 ft.
By indirect radiation.	40 to 50 "	50 to 70 "	100 to 140 "

Isolated buildings exposed to prevailing north or west winds should have a generous addition made to the heating-surface on their exposed sides.

The following rule is given in the catalogue of the Babcock & Wilcox Co., and is also recommended by the Nason Mfg. Co.:

Radiating surface may be calculated by the rule: Add together the square feet of glass in the windows, the number of cubic feet of air required to be changed per minute, and one twentieth the surface of external wall and roof; multiply this sum by the difference between the required temperature of the room and that of the external air at its lowest point, and divide the product by the difference in temperature between the steam in the pipes and the required temperature of the room. The quotient is the required radiating-surface in square feet.

Prof. R. C. Carpenter (*Heating and Ventilation*, Feb. 15, 1897), gives the following handy formula for the amount of heat required for heating buildings by direct radiation:

$$h = \frac{n}{55} C + G + \frac{1}{4}W,$$

in which  $W$  = wall-surface,  $G$  = glass- or window-surface, both in sq. ft.,  $C$  = contents of building in cu. ft.,  $n$  = number of times the air must be changed per hour, and  $h$  = total heat units required per degree of difference of temperature between the room and the surrounding space. To heat the building to 70° F. when the outside temperature is 0°, 70 times the above quantity of heat will be required. Under ordinary conditions of pressure and temperature 1 sq. ft. of steam-heating surface will supply 280 heat units per hour, and 1 sq. ft. of hot-water heating surface 175 heat units per hour. The square feet of radiating-surface required under these conditions will be  $R = 0.25h$  for steam heating, and  $R = 0.4h$  for hot-water heating. Prof. Carpenter says that for residences it is safe to assume that the air of the principal living-rooms will change twice in an hour, that of the halls three times and that of the other rooms once per hour, under ordinary conditions.

**Overhead Steam-pipes.** (A. R. Wolff, *Stevens Indicator*, 1887.)—When the overhead system of steam-heating is employed, in which system direct radiating-pipes, usually  $1\frac{1}{4}$  in. in diam., are placed in rows overhead, suspended upon horizontal racks, the pipes running horizontally, and side by side, around the whole interior of the building, from 2 to 3 ft. from the walls, and from 2 to 4 ft. from the ceiling, the amount of  $1\frac{1}{4}$  in. pipe required, according to Mr. C. J. H. Woodbury, for heating mills (for which use this system is deservedly much in vogue), is about 1 ft. in length for every 90 cu. ft. of space. Of course a great range of difference exists, due to the special character of the operating machinery in the mill, both in respect to the amount of air circulated by the machinery, and also the aid to warming the room by the friction of the journals.

**Indirect Heating-surface.**—J. H. Kinealy, in *Heating and Ventilation*, May 15, 1894, gives the following formula, deduced from results of experiments by C. B. Richards, W. J. Baldwin, J. H. Mills, and others, upon indirect heaters of various kinds, supplied with varying amounts of air per hour per square foot of surface:

$$N = \frac{35.04}{\frac{T_2 - T_1}{T_0 - T_1} - 0.369}; \quad T_2 = (T_0 - T_1) \left( 0.369 + \frac{35.04}{N} \right) + T_1.$$

$N$  = cubic feet of air, reduced to 70° F., supplied to the heater per square foot of heating-surface per hour;  $T_0$  = temperature of the steam or water in the heater;  $T_1$  = temperature of the air when it enters the heater;  $T_2$  = temperature of the air when it leaves the heater.

As the formula is based upon an average of experiments made upon all sorts of indirect heaters, the results obtained by the use of the equation may in some cases be slightly too small and in others slightly too large, although the error will in no case be great. No single formula ought to be expected to apply equally well to all dispositions of heating-surface in indirect heaters, as the efficiency of such heater can be varied between such wide limits by the construction and arrangement of the surface.

In indirect heating, the efficiency of the radiating-surface will increase, and the temperature of the air will diminish, when the quantity of the air caused to pass through the coil increases. Thus 1 sq. ft. radiating-surface, with steam at 212°, has been found to heat 100 cu. ft. of air per hour from zero to 150°, or 300 cu. ft. from zero to 100° in the same time. The best results are attained by using indirect radiation to supply the necessary ventilation, and direct radiation for the balance of the heat. (*Steam.*)

In indirect steam-heating the least flue area should be 1 to 1¼ sq. in. to every square foot of heating-surface, provided there are no long horizontal reaches in the duct, with little rise. The register should have twice the area of the duct to allow for the fretwork. For hot water heating from 25% to 30% more heating-surface and flue area should be given than for low-pressure steam. (*Engineering Record*, May 26, 1891.)

**Boiler Heating-surface Required.** (A. R. Wolff, *Stevens Indicator*, 1887.)—When the direct system is used to heat buildings in which the street floor is a store, and the upper floors are devoted to sales and stock-rooms and to light manufacturing, and in which the fronts are of stone or iron, and the sides and the rear of building of brick—a safe rule to follow is to supply 1 sq. ft. of boiler heating-surface for each 700 cu. ft., and 1 sq. ft. of radiating-surface for each 100 cu. ft. of contents of building.

For heating mills, shops, and factories, 1 sq. ft. of boiler heating-surface should be supplied for each 475 cu. ft. of contents of building; and the same allowance should also be made for heating exposed wooden dwellings. For heating foundries and wooden shops, 1 sq. ft. of boiler heating-surface should be provided for each 400 cu. ft. of contents; and for structures in which glass enters very largely in the construction—such as conservatories, exhibition buildings, and the like—1 sq. ft. of boiler heating-surface should be provided for each 275 cu. ft. of contents of building.

When the indirect system is employed, the radiator-surface and the boiler capacity to be provided will each have to be, on an average, about 25% more than where direct radiation is used. This percentage also marks approximately the increased fuel consumption in the indirect system.

*Steam* (Babcock & Wilcox Co.) has the following: 1 sq. ft. of boiler-surface will supply from 7 to 10 sq. ft. of radiating-surface, depending upon the size of boiler and the efficiency of its surface, as well as that of the radiating-surface. Small boilers for house use should be much larger proportionately than large plants. Each horse-power of boiler will supply from 240 to 360 ft. of 1-in. steam-pipe, or 80 to 120 sq. ft. of radiating-surface. Cubic feet of space has little to do with amount of steam or surface required, but is a convenient factor for rough calculations. Under ordinary conditions 1 horse-power will heat, approximately, in—

Brick dwellings, in blocks, as in cities... ..	15,000	to	20,000	cu. ft.
“ stores “ “ .....	10,000	“	15,000	“
“ dwellings, exposed all round.....	10,000	“	15,000	“
“ mills, shops, factories, etc.....	7,000	“	10,000	“
Wooden dwellings, exposed.....	7,000	“	10,000	“
Foundries and wooden shops.....	6,000	“	10,000	“
Exhibition buildings, largely glass, etc.....	4,000	“	15,000	“

For other resistances and pressures above atmosphere multiply by the respective factors below:

Water col..	6 in.	12 in.	24 in.	Press. ab. atm.	0 lbs.	3 lbs.	30 lbs.	60 lbs.
Multiply by	0.8027	0.6988	0.6084	Multiply by	1.023	1.015	0.973	0.948

**Registers and Cold-air Ducts for Indirect Steam Heating.**

--The *Locomotive* gives the following table of openings for registers and cold-air ducts, which has been found to give satisfactory results. The cold-air boxes should have  $1\frac{1}{2}$  sq. in. area for each square foot of radiator surface, and never less than  $\frac{3}{4}$  the sectional area of the hot-air ducts. The hot-air ducts should have 2 sq. in. of sectional area to each square foot of radiator surface on the first floor, and from  $1\frac{1}{2}$  to 2 inches on the second floor.

Heating Surface in Stacks.	Cold-air Supply, First Floor.	Size Register.	Cold-air Supply, 2d Floor.
30 square feet	45 square inches = inches	inches	inches
40 " "	60 " " = 5 by 9	9 by 12	4 by 10
50 " "	75 " " = 6 by 10	10 by 14	4 by 14
60 " "	90 " " = 8 by 10	10 by 14	5 by 15
70 " "	108 " " = 9 by 10	12 by 15	6 by 15
80 " "	120 " " = 9 by 12	12 by 19	6 by 18
90 " "	135 " " = 10 by 12	12 by 22	8 by 15
100 " "	150 " " = 11 by 12	14 by 24	9 by 15
		16 by 20	12 by 12

The sizes in the table approximate to the rules given, and it will be found that they will allow an easy flow of air and a full distribution throughout the room to be heated.

**Size of Steam Pipes for Steam Heating.** (See also Flow of Steam in Pipes.)—*Sizes of vertical main pipes. Direct radiation.* (J. R. Willett, *Heating and Ventilation*, Feb., 1894.)

Diameter of pipe, inches. 1 1¼ 1½ 2 2½ 3 3½ 4 5 6  
Sq. ft. of radiator surface 40 70 110 220 360 560 810 1110 2000 3000

A horizontal branch pipe for a given extent of radiator surface should be one size larger than a vertical pipe for the same surface.

The Nason Mfg. Co. gives the following:

Diameter of pipe, in ... .. 1¼ 1½ 2 2½ 3 3½  
Radiator surface sq ft. (maximum).. 125 200 500 1000 1500 2500

When mains and surfaces are very much above the boiler the pipes need not be as large as given above; under very favorable circumstances and

conditions a 4-inch pipe may supply from 2000 to 2500 sq. ft. of surface, a 6-inch pipe for 5000 sq. ft., and a 10-inch pipe for 15,000 to 20,000 sq. ft., if the distance of run from boiler is not too great. Less than 1½-inch pipe should not be used horizontally in a main unless for a single radiator connection.

*Steam*, by the Babcock & Wilcox Co., says: Where the condensed water is returned to the boiler, or where low pressure of steam is used, the diameter of mains leading from the boiler to the radiating-surface should be equal in inches to one tenth the square root of the radiating-surface, mains included, in square feet. Thus a 1-inch pipe will supply 100 square feet of surface, itself included. Return-pipes should be at least ¾ inch in diameter, and never less than one half the diameter of the main—longer returns requiring larger pipe. A thorough drainage of steam-pipes will effectually prevent all cracking and pounding noises therein.

*A. R. Wolff's Practice.*—Mr. Wolff gives the following figures showing his present practice (1897) in proportioning mains and returns. They are based on an estimated loss of pressure of 2% for a length of 100 ft. of pipe, not including allowance for bends and valves (see p. 678). For longer runs divide the thermal units given in the table by 0.1  $\sqrt{\text{length in ft.}}$ . Besides giving the thermal units the table also indicates the amount of direct radiating surface which the steam-pipes can supply, on the basis of an emission of 250 thermal units per hour for each square foot of direct radiating surface.

**Heating a Greenhouse by Steam.**—Wm. J. Baldwin answers a question in the *American Machinist* as below: With five pounds steam-pressure, how many square feet or inches of heating-surface is necessary to heat 100 square feet of glass on the roof, ends, and sides of a greenhouse in order to maintain a night heat of 55° to 65°, while the thermometer outside ranges at from 15° to 20° below zero; also, what boiler-surface is necessary? Which is the best for the purpose to use—2" pipe or 1¼" pipe?

*Ans.*—Reliable authorities agree that 1.25 to 1.50 cubic feet of air in an enclosed space will be cooled per minute per sq. ft. of glass as many degrees as the internal temperature of the house exceeds that of the air outside. Between + 65° and - 20° there will be a difference of 85°, or, say, one cubic foot of air cooled 127.5° F. for each sq. ft. of glass for the most extreme condition mentioned. Multiply this by the number of square feet of glass and by 60, and we have the number of cubic feet of air cooled 1° per hour within the building or house. Divide the number thus found by 48, and it gives the units of heat required, approximately. Divide again by 953, and it will give the number of pounds of steam that must be condensed from a pressure and temperature of five pounds above atmosphere to water at the same temperature in an hour to maintain the heat. Each square foot of surface of pipe will condense from ¼ to nearly ½ lb. of steam per hour, according as the coils are exposed or well or poorly arranged, for which an average of ⅓ lb. may be taken. According to this, it will require 3 sq. ft. of pipe surface per lb. of steam to be condensed. Proportion the heating-surface of the boiler to have about one fifth the actual radiating-surface, if you wish to keep steam over night, and proportion the grate to burn not more than six pounds of coal per sq. ft. of grate per hour. With very slow combustion, such as takes place in base-burning boilers, the grate might be proportioned for four to five pounds of coal per hour. It is cheaper to make coils of 1¼" pipe than of 2", and there is nothing to be gained by using 2" pipe unless the coils are very long. The pipes in a greenhouse should be

under or in front of the benches, with every chance for a good circulation of air. "Header" coils are better than "return-bend" coils for this purpose.

Mr. Baldwin's rule may be given the following form: Let  $H$  = heat-units transferred per hour,  $T$  = temperature inside the greenhouse,  $t$  = temperature outside,  $S$  = sq. ft. of glass surface; then  $H = 1.5S(T - t) \times 60 \div 48 = 1.875S(T - t)$ . Mr. Wolff's coefficient  $K$  for single skylights would give  $H = 1.118S(T - t)$ .

**Heating a Greenhouse by Hot Water.**—W. M. Mackay, of the Richardson & Boynton Co., in a lecture before the Master Plumbers' Association, N. Y., 1889, says: I find that while greenhouses were formerly heated by 4-inch and 3-inch cast-iron pipe, on account of the large body of water which they contained, and the supposition that they gave better satisfaction and a more even temperature, florists of long experience who have tried 4-inch and 3-inch cast-iron pipe, and also 2-inch wrought-iron pipe for a number of years in heating their greenhouses by hot water, and who have also tried steam-heat, tell me that they get better satisfaction, greater economy, and are able to maintain a more even temperature with 2-inch wrought-iron pipe and hot water than by any other system they have used. They attribute this result principally to the fact that this size pipe contains less water and on this account the heat can be raised and lowered quicker than by any other arrangement of pipes, and a more uniform temperature maintained than by steam or any other system.

### HOT-WATER HEATING.

(Nason Mfg. Co.)

There are two distinct forms or modifications of hot-water apparatus, depending upon the temperature of the water.

In the first or open-tank system the water is never above 212° temperature, and rarely above 200°. This method always gives satisfaction where the surface is sufficiently liberal, but in making it so its cost is considerably greater than that for a steam-heating apparatus.

In the second method, sometimes called (erroneously) high-pressure hot-water heating, or the closed-system apparatus, the tank is closed. If it is provided with a safety-valve set at 10 lbs. it is practically as safe as the open-tank system.

**Law of Velocity of Flow.**—The motive power of the circulation in a hot-water apparatus is the difference between the specific gravities of the water in the ascending and the descending pipes. This effective pressure is very small, and is equal to about one grain for each foot in height for each degree difference between the pipes; thus, with a height of 12' in "up" pipe, and a difference between the temperatures of the up and down pipes of 8°, the difference in their specific gravities is equal to 8.16 grains on each square inch of the section of return-pipe, and the velocity of the circulation is proportioned to these differences in temperature and height.

**To Calculate Velocity of Flow.**—Thus, with a height of ascending pipe equal to 10' and a difference in temperatures of the flow and return pipes of 8°, the difference in their specific gravities will equal 81.6 grains, or  $\div 7000 = .01166$  lbs., or  $\times 2.31$  (feet of water in one pound) = .0269 ft., and by the law of falling bodies the velocity will be equal to  $8 \sqrt{.0269} = 1.312$  ft. per second, or  $\times 60 = 78.7$  ft. per minute. In this calculation the effect of friction is entirely omitted. Considerable deduction must be made on this account. Even in apparatus where length of pipe is not great, and with pipes of larger areas and with few bends or angles, a large deduction for friction must be made from the theoretical velocity, while in large and complex apparatus with small head, the velocity is so much reduced by friction that sometimes as much as from 50% to 90% must be deducted to obtain the true rate of circulation.

Main flow-pipes from the heater, from which branches may be taken, are to be preferred to the practice of taking off nearly as many pipes from the heater as there are radiators to supply.

It is not necessary that the main flow and return pipes should equal in capacity that of all their branches. The hottest water will seek the highest level, while gravity will cause an even distribution of the heated water if the surface is properly proportioned.

It is good practice to reduce the size of the vertical mains as they ascend, say at the rate of one size for each floor.

As with steam, so with hot water, the pipes must be unconfined to allow

for expansion of the pipes consequent on having their temperatures increased.

An expansion tank is required to keep the apparatus filled with water, which latter expands  $1/24$  of its bulk on being heated from  $40^{\circ}$  to  $212^{\circ}$ , and the cistern must have capacity to hold certainly this increased bulk. It is recommended that the supply cistern be placed on level with or above the highest pipes of the apparatus, in order to receive the air which collects in the mains and radiators, and capable of holding at least  $1/20$  of the water in the entire apparatus.

**Approximate Proportions of Radiating-surfaces to Cubic Capacities of Space to be Heated.**

One Square Foot of Radiating-surface will heat with—	In Dwellings, School-rooms, Offices, etc.	In Halls, Stores, Lofts, Factories, etc.	In Churches, Large Auditoriums, etc.
High temperature direct hot-water radiation .....	50 to 70 cu. ft.	65 to 90 cu. ft.	130 to 180 cu. ft.

The best forms of hot-water-heating boilers are proportioned about as follows:

1 sq. ft. of grate-surface to about 40 sq. ft. of boiler-surface.
1 " " boiler- " " 5 " " radiating-surface.
1 " " grate- " " 200 " " " "

**Rules for Hot-water Heating.**—J. L. Saunders (Heating and Ventilation, Dec. 15, 1894) gives the following: Allow 1 sq. ft. of radiating surface for every 3 ft. of glass surface, and 1 sq. ft. for every 30 sq. ft. of wall surface, also 1 sq. ft. for the following numbers of cubic feet of space in the several cases mentioned.

In dwelling-houses: Libraries and dining-rooms, first floor..	35 to 40 cu ft.
Reception halls, first floor.....	40 to 50 " "
Stair halls, " " .....	40 to 55 " "
Chambers above, " " .....	50 to 65 " "
Libraries, sewing-rooms, nurseries, etc., above first floor.....	45 to 55 " "
Bath-rooms.....	30 to 40 " "
Public-school rooms.....	60 to 85 " "
Offices.....	50 to 65 " "
Factories and stores.....	65 to 90 " "
Assembly halls and churches.....	90 to 150 " "

To find the necessary amount of indirect radiation required to heat a room: Find the required amount of direct radiation according to the foregoing method and add 50%. This if wrought-iron pipe coil surface is used; if cast-iron pin indirect-stack surface is used it is advisable to add from 70% to 80%.

*Sizes of hot-air flues, cold-air ducts, and registers for indirect work.*—Hot-air flues, first floor: Make the net internal area of the flue equal to  $\frac{3}{4}$  sq. in. to every square foot of radiating surface in the indirect stack. Hot-air flues, second floor: Make the net internal area of the flue equal to  $\frac{5}{8}$  sq. in. to every square foot of radiating surface in the indirect stack.

*Cold-air ducts, first floor:* Make the net internal area of the duct equal to  $\frac{5}{8}$  sq. in. to every square foot of radiating surface in the indirect stack. Cold air ducts, second floor: Make the net internal area of the duct equal to  $\frac{1}{2}$  sq. in. to every square foot of radiating surface in the indirect stack.

*Hot-air registers* should have their net area equal in full to the area of the hot-air flues. Multiply the length by the width of the register in inches;  $\frac{2}{3}$  of the product is the net area of register.

**Arrangement of Mains for Hot-water Heating.** (W. M. Mackay, Lecture before Master Plumbers' Assoc., N. Y., 1889)—There are two different systems of mains in general use, either of which, if properly placed, will give good satisfaction. One is the taking of a single large-flow main from the heater to supply all the radiators on the several floors, with a corresponding return main of the same size. The other is the taking of a number of 2-inch wrought-iron mains from the heater, with the same number of return mains of the same size, branching off to the several radiators or coils with  $\frac{1}{4}$ -inch or 1-inch pipe, according to the size of the radiator or coil. A 2-inch main will supply three  $\frac{1}{4}$ -inch or four 1-inch branches, and these branches should be taken from the top of the horizontal main with a nipple and elbow, except in special cases where it is found necessary to retard the flow of water to the near radiator, for the purpose of assisting the circulation in the far radiator; in this case the branch is taken from the side of the horizontal main. The flow and return mains are usually run side by side, suspended from the basement ceiling, and should have a gradual ascent from the heater to the radiators of at least 1 inch in 10 feet. It is customary, and an advantage where 2-inch mains are used, to reduce the size of the main at every point where a branch is taken off.

The single or large main system is best adapted for large buildings; but there is a limit as to size of main which it is not wise to go beyond—generally 6-inch, except in special cases.

The proper area of cold-air pipe necessary for 100 square feet of indirect radiation in hot-water heating is 75 square inches, while the hot-air pipe should have at least 100 square inches of area. There should be a damper in the cold-air pipe for the purpose of controlling the amount of air admitted to the radiator, depending on the severity of the weather.

**THE BLOWER SYSTEM OF HEATING AND VENTILATING.**

The system provides for the use of a fan or blower which takes its supply of fresh air from the outside of the building to be heated, forces it over steam coils, located either centrally or divided up into a number of independent groups, and then into the several ducts or flues leading to the various rooms. The movement of the warmed air is positive, and the delivery of the air to the various points of supply is certain and entirely independent of atmospheric conditions. For engines, fans, and steam-coils used with the blower system, see page 519.

**Experiments with Radiators of 60 sq. ft. of Surface.** (*Mech. News*, Dec., 1893.)—After having determined the volume and temperature of the warm air passing through the flues and radiators from natural causes, a fan was applied to each flue, forcing in air, and new sets of measurements were made. The results showed that more than two and one-third times as much air was warmed with the fans in use, and the falling off in the temperature of this greatly increased air-volume was only about 12.6%. The condensation of steam in the radiators with the forced-air circulation also was only 66% greater than with natural-air draught. One of the several sets of test figures obtained is as follows :

	Natural Draught in Flue.	Forced-air Circulation.
Cubic feet of air per minute . . . . .	457.5	1227
Condensation of steam per minute in ounces . . . . .	11.7	19.6
Steam pressure in radiator, pounds . . . . .	9	9
Temperature of air after leaving radiator . . . . .	142°	124°
“ “ “ before passing through radiator. . . . .	61°	61°
Amount of radiating surface in square feet . . . . .	60	60
Size of flue in both cases . . . . .	12 x 18 inches.	

There was probably an error in the determination of the volume of air in these tests, as appears from the following calculation. (W. K.) Assume that 1 lb. of steam in condensing from 9 lbs. pressure and cooling to the temperature at which the water may have been discharged from the radiator gave up 1000 heat-units, or 62.5 h. u. per ounce; that the air weighed .076 lb. per cubic foot, and that its specific heat is .238. We have

	Natural Draught.	Forced Draught.
Heat given up by steam, ounces x 62.5 . . . . . =	731	1225 H.U.
Heat received by air, cu. ft. x .076 x diff. of tem. x .238 =	673	1399 “

Or, in the case of forced draught the air received 14% more heat than the steam gave out, which is impossible. Taking the heat given up by the steam as the correct measure of the work done by the radiator, the temperature of the steam at 237°, and the average temperature of the air in the case of natural draught at 102° and in the other case at 93°, we have for the temperature difference in the two cases 135° and 144° respectively; dividing these into the heat-units we find that each square foot of radiating surface transmitted 5.4 heat-units per hour per degree of difference of temperature, in the case of natural draught, and 8.5 heat-units in the case of forced draught (= 8.5 x 144° = 1224 heat-units per square foot of surface).

In the Women's Homœopathic Hospital in Philadelphia, 2000 feet of one-inch pipe heats 250,000 cubic feet of space, ventilating as well; this equals one square foot of pipe surface for about 350 cubic feet of space, or less than 3 square feet for 1000 cubic feet. The fan is located in a separate building about 100 feet from the hospital, and the air, after being heated to about 135°, is conveyed through an underground brick duct with a loss of only five or six degrees in cold weather. (H. I. Snell, *Trans. A. S. M. E.* ix. 106.)

**Heating a Building to 70° F. Inside when the Outside Temperature is Zero.**—It is customary in some contracts for heating to guarantee that the apparatus will heat the interior of the building to 70° in zero weather. As it may not be practicable to obtain zero weather for the purpose of a test, it may be difficult to prove the performance of the guarantee. E. E. Macgovern, in *Engineering Record*, Feb. 3, 1894, gives a calculation tending to show that a test may be made in weather of a higher temperature than zero, if the heat of the interior is raised above 70°. The higher the temperature of the rooms the lower is the efficiency of the radiating-surface, since the efficiency depends upon the difference between the

temperature inside of the radiator and the temperature of the room. He concludes that a heating apparatus sufficient to heat a given building to 70° in zero weather with a given pressure of steam will be found to heat the same building, steam-pressure constant, to 110° at 60°, 95° at 50°, 82° at 40°, and 74° at 32°, outside temperature. The accuracy of these figures, however has not been tested by experiment.

The following solution of the question is proposed by the author. It gives results quite different from those of Mr. Macgovern, but, like them, lacks experimental confirmation.

- Let  $S$  = sq. ft. of surface of the steam or hot-water radiator;
- $W$  = sq. ft. of surface of exposed walls, windows, etc.;
- $T_s$  = temp. of the steam or hot water,  $T_1$  = temp. of inside of building or room,  $T_0$  = temp. of outside of building or room;
- $a$  = heat-units transmitted per sq. ft. of surface of radiator per hour per degree of difference of temperature;
- $b$  = average heat-units transmitted per sq. ft. of walls per hour, per degree of difference of temperature, including allowance for ventilation.

It is assumed that within the range of temperatures considered Newton's law of cooling holds good, viz., that it is proportional to the difference of temperature between the two sides of the radiating-surface.

Then  $aS(T_s - T_1) = bW(T_1 - T_0)$ . Let  $\frac{bW}{aS} = C$ ; then

$$T_s - T_1 = C(T_1 - T_0); \quad T_1 = \frac{T_s + CT_0}{1 + C}; \quad C = \frac{T_s - T_1}{T_1 - T_0}.$$

If  $T_1 = 70$ , and  $T_0 = 0$ ,  $C = \frac{T_s - 70}{70}$ .

Let $T_s = 140^\circ$ ,	213.5°,	308°;
Then $C = 1$ ,	2.05,	3.4.

From these we derive the following:

Temperature of Steam or Hot Water, $T_s$ .	Outside Temperatures, $T_0$ .						
	- 20°	- 10°	0°	10°	20°	30°	40°
	Inside Temperatures, $T_1$ .						
140°	60	65	70	75	80	85	90
213.5	56.6	63.3	70	76.7	83.4	90.2	96.9
308	54.5	62.3	70	77.7	85.5	93.2	100.9

**Heating by Electricity.**—If the electric currents are generated by a dynamo driven by a steam-engine, electric heating will prove very expensive, since the steam-engine wastes in the exhaust-steam and by radiation about 90% of the heat-units supplied to it. In direct steam-heating, with a good boiler and properly covered supply-pipes, we can utilize about 60% of the total heat value of the fuel. One pound of coal, with a heating value of 13,000 heat-units, would supply to the radiators about  $13,000 \times .60 = 7800$  heat-units. In electric heating, suppose we have a first-class condensing-engine developing 1 H.P. for every 2 lbs. of coal burned per hour. This would be equivalent to  $1,980,000 \text{ ft.-lbs.} \div 778 = 2545$  heat-units, or 1272 heat-units for 1 lb. of coal. The friction of the engine and of the dynamo and the loss by electric leakage, and by heat radiation from the conducting wires, might reduce the heat-units delivered as electric current to the electric radiator, and these converted into heat to 50% of this, or only 636 heat-units, or less than one twelfth of that delivered to the steam-radiators in direct steam-heating. Electric heating, therefore, will prove uneconomical unless the electric current is derived from water or wind power, which would otherwise be wasted. (See Electrical Engineering.)

**WATER.**

**Expansion of Water.**—The following table gives the relative volumes of water at different temperatures, compared with its volume at 4° C. according to Kopp, as corrected by Porter.

Cent.	Fahr.	Volume.	Cent.	Fahr.	Volume.	Cent.	Fahr.	Volume.
4°	39.1°	1.00000	35°	95°	1.00586	70°	158°	1.02241
5	41	1.00001	40	104	1.00767	75	167	1.02548
10	50	1.00025	45	113	1.00967	80	176	1.02872
15	59	1.00083	50	122	1.01186	85	185	1.03213
20	68	1.00171	55	131	1.01423	90	194	1.03570
25	77	1.00286	60	140	1.01678	95	203	1.03943
30	86	1.00425	65	149	1.01951	100	212	1.04332

Weight of 1 cu. ft. at 39.1° F. = 62.4245 lb. ÷ 1.04332 = 59.833, weight of 1 cu. ft. at 212° F.

**Weight of Water at Different Temperatures.**—The weight of water at maximum density, 39.1°, is generally taken at the figure given by Rankine, 62.425 lbs. per cubic foot. Some authorities give as low as 62.379. The figure 62.5 commonly given is approximate. The highest authoritative figure is 62.425. At 62° F. the figures range from 62.291 to 62.360. The figure 62.355 is generally accepted as the most accurate.

At 32° F. figures given by different writers range from 62.379 to 62.418. Clark gives the latter figure, and Hamilton Smith, Jr., (from Rosetti,) gives 62.416.

**Weight of Water at Temperatures above 212° F.**—Porter (Richards' "Steam-engine Indicator," p. 52) says that nothing is known about the expansion of water above 212°. Applying formulæ derived from experiments made at temperatures below 212°, however, the weight and volume above 212° may be calculated, but in the absence of experimental data we are not certain that the formulæ hold good at higher temperatures.

Thurston, in his "Engine and Boiler Trials," gives a table from which we take the following (neglecting the third decimal place given by him):

Temperature, deg. F.	Weight, lbs. per cubic foot.	Temperature, deg. F.	Weight, lbs. per cubic foot.	Temperature, deg. F.	Weight, lbs. per cubic foot.	Temperature, deg. F.	Weight, lbs. per cubic foot.	Temperature, deg. F.	Weight, lbs. per cubic foot.
212	59.71	280	57.90	350	55.52	420	52.86	490	50.03
220	59.64	290	57.59	360	55.16	430	52.47	500	49.61
230	59.37	300	57.26	370	54.79	440	52.07	510	49.20
240	59.10	310	56.93	380	54.41	450	51.66	520	48.78
250	58.81	320	56.58	390	54.03	460	51.26	530	48.36
260	58.52	330	56.24	400	53.64	470	50.85	540	47.94
270	58.21	340	55.88	410	53.26	480	50.44	550	47.52

Box on Heat gives the following :

Temperature F.....	212°	250°	300°	350°	400°	450°	500°	600°
Lbs. per cubic foot....	59.82	58.85	57.42	55.94	54.34	52.70	51.02	47.64

At 212° figures given by different writers (see Trans. A. S. M. E., xiii. 409) range from 59.56 to 59.845, averaging about 59.77.

**Weight of Water per Cubic Foot, from 32° to 212° F., and heat-units per pound, reckoned above 32° F.:** The following table, made by interpolating the table given by Clark as calculated from Rankine's formula, with corrections for apparent errors, was published by the author in 1884, Trans. A. S. M. E., vi. 90. (For heat units above 212° see Steam Tables.)

Temp., deg. F.	Weight, lbs. per cubic foot.	Heat-units.	Temperature, deg. F.	Weight, lbs. per cubic foot.	Heat-units.	Temperature, deg. F.	Weight, lbs. per cubic foot.	Heat-units.	Temperature, deg. F.	Weight, lbs. per cubic foot.	Heat-units.

### Comparison of Heads of Water in Feet with Pressures in Various Units.

One foot of water at 39°.1 Fahr. = 62.425 lbs. on the square foot;  
 " " " = 0.4335 lbs. on the square inch;  
 " " " = 0.0295 atmosphere;  
 " " " = 0.8826 inch of mercury at 32°;  
 " " " = 773.3 } feet of air at 32° and  
 atmospheric pressure;

One lb. on the square foot, at 39°.1 Fahr..... = 0.01602 foot of water;  
 One lb. on the square inch ..... = 2.307 feet of water;  
 One atmosphere of 29.922 inches of mercury.... = 33.9 " " "  
 One inch of mercury at 32°.1..... = 1.133 " " "  
 One foot of air at 32 deg., and one atmosphere.. = 0.001293 " " "  
 One foot of average sea-water..... = 1.026 foot of pure water;  
 One foot of water at 62° F..... = 62.355 lbs. per sq. foot;  
 " " " " " 62° F..... = 0.43302 lb. per sq. inch;  
 One inch of water at 62° F..... = 0.5774 ounce = 0.036085 lb. per sq. inch;  
 One pound of water on the square inch at 62° F. = 2.3094 feet of water.  
 One ounce of water on the square inch at 62° F. = 1.732 inches of water.

**Pressure in Pounds per Square Inch for Different Heads of Water.**

At 62° F. 1 foot head = 0.433 lb. per square inch, .433 × 144 = 62.352 lbs. per cubic foot.

Head, feet.	0	1	2	3	4	5	6	7	8	9

**Pressure of Water due to its Weight.**—The pressure of still water in pounds per square inch against the sides of any pipe, channel, or vessel of any shape whatever is due solely to the "head," or height of the level surface of the water above the point at which the pressure is considered, and is equal to .43302 lb. per square inch for every foot of head, or 62.355 lbs. per square foot for every foot of head (at 62° F.).

The pressure per square inch is equal in all directions, downwards, upwards, or sideways, and is independent of the shape or size of the containing vessel.

The pressure against a vertical surface, as a retaining-wall, at any point is in direct ratio to the head above that point, increasing from 0 at the level surface to a maximum at the bottom. The total pressure against a vertical strip of a unit's breadth increases as the area of a right-angled triangle

whose perpendicular represents the height of the strip and whose base represents the pressure on a unit of surface at the bottom; that is, it increases as the square of the depth. The sum of all the horizontal pressures is represented by the area of the triangle, and the resultant of this sum is equal to this sum exerted at a point one third of the height from the bottom. (The centre of gravity of the area of a triangle is one third of its height.)

The horizontal pressure is the same if the surface is inclined instead of vertical.

(For an elaboration of these principles see Trautwine's Pocket-Book, or the chapter on Hydrostatics in any work on Physics. For dams, retaining-walls, etc., see Trautwine.)

The amount of pressure on the interior walls of a pipe has no appreciable effect upon the amount of flow.

**Buoyancy.**—When a body is immersed in a liquid, whether it float or sink, it is buoyed up by a force equal to the weight of the bulk of the liquid displaced by the body. The weight of a floating body is equal to the weight of the bulk of the liquid that it displaces. The upward pressure or buoyancy of the liquid may be regarded as exerted at the centre of gravity of the displaced water, which is called the centre of pressure or of buoyancy. A vertical line drawn through it is called the axis of buoyancy or of flotation. In a floating body at rest a line joining the centre of gravity and the centre of buoyancy is vertical, and is called the axis of equilibrium. When an external force causes the axis of equilibrium to lean, if a vertical line be drawn upward from the centre of buoyancy to this axis, the point where it cuts the axis is called the *metacentre*. If the metacentre is above the centre of gravity the distance between them is called the metacentric height, and the body is then said to be in stable equilibrium, tending to return to its original position when the external force is removed.

**Boiling-point.**—Water boils at  $212^{\circ}$  F. ( $100^{\circ}$  C.) at mean atmospheric pressure at the sea-level, 14.696 lbs. per square inch. The temperature at which water boils at any given pressure is the same as the temperature of saturated steam at the same pressure. For boiling-point of water at other pressure than 14.696 lbs. per square inch, see table of the Properties of Saturated Steam.

**The Boiling-point of Water may be Raised.**—When water is entirely freed of air, which may be accomplished by freezing or boiling, the cohesion of its atoms is greatly increased, so that its temperature may be raised over  $50^{\circ}$  above the ordinary boiling-point before ebullition takes place. It was found by Faraday that when such air-freed water did boil, the rupture of the liquid was like an explosion. When water is surrounded by a film of oil, its boiling temperature may be raised considerably above its normal standard. This has been applied as a theoretical explanation in the instance of boiler-explosions.

The freezing-point also may be lowered, if the water is perfectly quiet, to  $-10^{\circ}$  C., or  $18^{\circ}$  Fahrenheit below the normal freezing-point. (Hamilton Smith, Jr., on Hydraulics, p. 13.) The density of water at  $14^{\circ}$  F. is .99814, its density at  $39^{\circ}$  being 1, and at  $32^{\circ}$ , .99987.

**Freezing-point.**—Water freezes at  $32^{\circ}$  F. at the ordinary atmospheric pressure, and ice melts at the same temperature. In the melting of 1 pound of ice into water at  $32^{\circ}$  F. about 142 heat-units are absorbed, or become latent; and in freezing 1 lb. of water into ice a like quantity of heat is given out to the surrounding medium.

**Sea-water** freezes at  $27^{\circ}$  F. The ice is fresh. (Trautwine.)

**Ice and Snow.** (From Clark.)—1 cubic foot of ice at  $32^{\circ}$  F. weighs 57.50 lbs.; 1 pound of ice at  $32^{\circ}$  F. has a volume of .0174 cu. ft. = 30.067 cu. in.

Relative volume of ice to water at  $32^{\circ}$  F., 1.0855, the expansion in passing into the solid state being 8.55%. Specific gravity of ice = 0.922, water at  $62^{\circ}$  F. being 1.

At high pressures the melting-point of ice is lower than  $32^{\circ}$  F., being at the rate of  $.0133^{\circ}$  F. for each additional atmosphere of pressure

The specific heat of ice is .504, that of water being 1.

1 cubic foot of fresh snow, according to humidity of atmosphere: 5 lbs. to 12 lbs. 1 cubic foot of snow moistened and compacted by rain: 15 lbs. to 50 lbs. (Trautwine.)

**Specific Heat of Water.** (From Clark's Steam-engine.)—Calculated by means of Regnault's formula,  $c = 1 + 0.00004t + 0.0000009t^2$ , in which  $c$  is the specific heat of water at any temperature  $t$  in centigrade degrees, the specific heat at the freezing-point being 1.

**Compressibility of Water.**—Water is very slightly compressible. Its compressibility is from .000040 to .000051 for one atmosphere, decreasing with increase of temperature. For each foot of pressure distilled water will be diminished in volume .0000015 to .0000013. Water is so incompressible that even at a depth of a mile a cubic foot of water will weigh only about half a pound more than at the surface.

## THE IMPURITIES OF WATER.

(A. E. Hunt and G. H. Clapp, Trans. A. I. M. E. xvii. 338.)

Commercial analyses are made to determine concerning a given water: (1) its applicability for making steam; (2) its hardness, or the facility with which it will "form a lather" necessary for washing; or (3) its adaptation to other manufacturing purposes.

At the Buffalo meeting of the Chemical Section of the A. A. A. S. it was decided to report all water analyses in parts per thousand, hundred-thousand, and million.

To convert grains per imperial (British) gallons into parts per 100,000, divide by 0.7. To convert parts per 100,000 into grains per U. S. gallon, multiply by  $7/12$  or .583.

The most common commercial analysis of water is made to determine its fitness for making steam. Water containing more than 5 parts per 100,000 of free sulphuric or nitric acid is liable to cause serious corrosion, not only of the metal of the boiler itself, but of the pipes, cylinders, pistons, and valves with which the steam comes in contact.

The total residue in water used for making steam causes the interior linings of boilers to become coated, and often produces a dangerous hard scale, which prevents the cooling action of the water from protecting the metal against burning.

Lime and magnesia bicarbonates in water lose their excess of carbonic acid on boiling, and often, especially when the water contains sulphuric acid, produce, with the other solid residues constantly being formed by the evaporation, a very hard and insoluble scale. A larger amount than 100 parts per 100,000 of total solid residue will ordinarily cause troublesome scale, and should condemn the water for use in steam-boilers, unless a better supply cannot be obtained.

The following is a tabulated form of the causes of trouble with water for steam purposes, and the proposed remedies, given by Prof. L. M. Norton.

### CAUSES OF INCRUSTATION.

1. Deposition of suspended matter.
2. Deposition of deposited salts from concentration.
3. Deposition of carbonates of lime and magnesia by boiling off carbonic acid, which holds them in solution.

4. Deposition of sulphates of lime, because sulphate of lime is but slightly soluble in cold water, less soluble in hot water, insoluble above 270° F.
5. Deposition of magnesia, because magnesium salts decompose at high temperature.
6. Deposition of lime soap, iron soap, etc., formed by saponification of grease.

#### MEANS FOR PREVENTING INCRUSTATION.

1. Filtration.
2. Blowing off.
3. Use of internal collecting apparatus or devices for directing the circulation.
4. Heating feed-water.
5. Chemical or other treatment of water in boiler.
6. Introduction of zinc into boiler.
7. Chemical treatment of water outside of boiler.

#### TABULAR VIEW.

Troublesome Substance.	Trouble.	Remedy or Palliation.
Sediment, mud, clay, etc.	Incrustation.	Filtration; blowing off.
Readily soluble salts.	"	Blowing off.
Bicarbonates of lime, magnesia, iron.	"	Heating feed. Addition of caustic soda, lime, or magnesia, etc.
Sulphate of lime.	"	Addition of carb. soda, barium hydrate, etc.
Chloride and sulphate of magnesium.	Corrosion.	Addition of carbonate of soda, etc.
Carbonate of soda in large amounts.	Priming.	Addition of barium chloride, etc.
Acid (in mine waters).	Corrosion.	Alkali.
Dissolved carbonic acid and oxygen.	Corrosion.	Feed milk of lime to the boiler, to form a thin internal coating.
Grease (from condensed water).	Corrosion or incrustation.	Different cases require different remedies. Consult a specialist on the subject.
Organic matter (sewage).	Priming, corrosion, or incrustation.	

The mineral matters causing the most troublesome boiler-scales are bicarbonates and sulphates of lime and magnesia, oxides of iron and alumina, and silica. The analyses of some of the most common and troublesome boiler-scales are given in the following table:

Many substances have been added with the idea of causing chemical action which will prevent boiler-scale. As a general rule, these do more harm than good, for a boiler is one of the worst possible places in which to carry on chemical reaction, where it nearly always causes more or less corrosion of the metal, and is liable to cause dangerous explosions.

In cases where water containing large amounts of total solid residue is necessarily used, a heavy petroleum oil, free from tar or wax, which is not acted upon by acids or alkalis, not having sufficient wax in it to cause saponification, and which has a vaporizing-point at nearly 600° F., will give the best results in preventing boiler-scale. Its action is to form a thin greasy film over the boiler linings, protecting them largely from the action of acids in the water and greasing the sediment which is formed, thus preventing the formation of scale and keeping the solid residue from the evaporation of the water in such a plastic suspended condition that it can be easily ejected from the boiler by the process of “blowing off.” If the water is not blown off sufficiently often, this sediment forms into a “putty” that will necessitate cleaning the boilers. Any boiler using bad water should be blown off every twelve hours.

**Hardness of Water.**—The hardness of water, or its opposite quality, indicated by the ease with which it will form a lather with soap, depends almost altogether upon the presence of compounds of lime and magnesia. Almost all soaps consist, chemically, of oleate, stearate, and palmitate, of an alkaline base, usually soda and potash. The more lime and magnesia in a sample of water, the more soap a given volume of the water will decompose, so as to give insoluble oleate, palmitate, and stearate of lime and magnesia, and consequently the more soap must be added to a gallon of water in order that the necessary quantity of soap may remain in solution to form the lather. The relative hardness of samples of water is generally expressed in terms of the number of standard soap-measures consumed by a gallon of water in yielding a permanent lather.

The standard soap-measure is the quantity required to precipitate one grain of carbonate of lime.

It is commonly reckoned that one gallon of pure distilled water takes one soap-measure to produce a lather. Therefore one is deducted from the total number of soap-measures found to be necessary to use to produce a lather in a gallon of water, in reporting the number of soap-measures, or “degrees” of hardness of the water sample. In actually making tests for hardness, the “miniature gallon,” or seventy cubic centimetres, is used rather than the inconvenient larger amount. The standard measure is made by completely dissolving ten grammes of pure castile soap (containing 60 per cent olive-oil) in a litre of weak alcohol (of about 35 per cent alcohol). This yields a solution containing exactly sufficient soap in one cubic centimeter of the solution to precipitate one milligramme of carbonate of lime, or, in other words, the standard soap solution is reduced to terms of the “miniature gallon” of water taken.

If a water charged with a bicarbonate of lime, magnesia, or iron is boiled,

it will, on the excess of the carbonic acid being expelled, deposit a considerable quantity of the lime, magnesia, or iron, and consequently the water will be softer. The hardness of the water after this deposit of lime, after long boiling, is called the *permanent hardness* and the difference between it and the total hardness is called *temporary hardness*.

Lime salts in water react immediately on soap-solutions, precipitating the oleate, palmitate, or stearate of lime at once. Magnesia salts, on the contrary, require some considerable time for reaction. They are, however, more powerful hardeners; one equivalent of magnesia salts consuming as much soap as one and one-half equivalents of lime.

The presence of soda and potash salts softens rather than hardens water. Each grain of carbonate of lime per gallon of water causes an increased expenditure for soap of about 2 ounces per 100 gallons of water. (*Eng'g News*, Jan. 31, 1885.)

**Purifying Feed-water for Steam-boilers.** (See also Incrustation and Corrosion, p. 716.)—When the water used for steam-boilers contains a large amount of scale-forming material it is usually advisable to purify it before allowing it to enter the boiler rather than to attempt the prevention of scale by the introduction of chemicals into the boiler. Carbonates of lime and magnesia may be removed to a considerable extent by simple heating of the water in an exhaust-steam feed-water heater or, still better, by a live-steam heater. (See circular of the Hoppes Mfg. Co., Springfield, O.) When the water is very bad it is best treated with chemicals—lime, soda-ash, caustic soda, etc.—in tanks, the precipitates being separated by settling or filtering. For a description of several systems of water purification see a series of articles on the subject by Albert A. Cary in *Eng'g Mag.*, 1897.

Mr. W. B. Coggsell, of the Solvay Process Co.'s Soda Works in Syracuse, N. Y., thus describes the system of purification of boiler feed-water in use at these works (*Trans. A. S. M. E.*, xiii. 255):

For purifying, we use a weak soda liquor, containing about 12 to 15 grams  $\text{Na}_2\text{CO}_3$  per litre. Say  $1\frac{1}{2}$  to 2  $\text{M}^3$  (or 397 to 530 gals.) of this liquor is run into the precipitating tank. Hot water about  $60^\circ \text{C}$ . is then turned in, and the reaction of the precipitation goes on while the tank is filling, which requires about 15 minutes. When the tank is full the water is filtered through the Hyatt (4), 5 feet diameter, and the Jewell (1), 10 feet diameter, filters in 30 minutes. Forty tanks treated per 24 hours.

Charge of water purified at once..... 35  $\text{M}^3$ , 9,275 gallons.  
Soda in purifying reagent..... 15 kgs.  $\text{Na}_2\text{CO}_3$ .  
Soda used per 1,000 gallons..... 3.5 lbs.

A sample is taken from each boiler every other day and tested for deg. Baumé, soda and salt. If the deg. B. is more than 2, that boiler is blown to reduce it below 2 deg. B.

The following are some analyses given by Mr. Coggsell:

	Lake Water, grams per litre.	Mud from Hyatt Filter.	Scale from Boiler-tube.	Scale found in Pump.
Calcium sulphate.....	.261	3.70	51.24	10.9
Calcium chloride....	.186	.....	.....	.....
Calcium carbonate.....	.091	63.37	19.76	87.

**Softening Hard Water for Locomotive Use.**—A water-softening plant in operation at Fossil, in Western Wyoming, on the Union Pacific Railway, is described in *Eng'g News*, June 9, 1892. It is the invention

of Arthur Pennell, of Kansas City. The general plan adopted is to first dissolve the chemicals in a closed tank, and then connect this to the supply main so that its contents will be forced into the main tank, the supply-pipe being so arranged that thorough mixture of the solution with the water is obtained. A waste-pipe from the bottom of the tank is opened from time to time to draw off the precipitate. The pipe leading to the tender is arranged to draw the water from near the surface.

A water-tank 24 feet in diameter and 16 feet high will contain about 46,600 gallons of water. About three hours should be allowed for this amount of water to pass through the tank to insure thorough precipitation, giving a permissible consumption of about 15,000 gallons per hour. Should more than this be required, auxiliary settling-tanks should be provided.

The chemicals added to precipitate the scale-forming impurities are sodium carbonate and quicklime, varying in proportions according to the relative proportions of sulphates and carbonates in the water to be treated. Sufficient sodium carbonate is added to produce just enough sodium sulphate to combine with the remaining lime and magnesia sulphate and produce glauberite or its corresponding magnesia salt, thereby to get rid of the sodium sulphate, which produces foaming, if allowed to accumulate.

For a description of a purifying plant established by the Southern Pacific R. R. Co. at Port Los Angeles, Cal., see a paper by Howard Stillmann in *Trans. A. S. M. E.*, vol. xix, Dec. 1897.

## HYDRAULICS—FLOW OF WATER.

**Formulae for Discharge of Water through Orifices and Weirs.**—For rectangular or circular orifices, with the head measured from centre of the orifice to the surface of the still water in the feeding reservoir.

$$Q = C \sqrt{2gH} \times a. \quad \dots \dots \dots (1)$$

For weirs with no allowance for increased head due to velocity of approach:

$$Q = C \frac{2}{3} \sqrt{2gH} \times LH. \quad \dots \dots \dots (2)$$

For rectangular and circular or other shaped vertical or inclined orifices; formula based on the proposition that each successive horizontal layer of water passing through the orifice has a velocity due to its respective head:

$$Q = cL \frac{2}{3} \sqrt{2g} \times (\sqrt{Hb^3} - \sqrt{Ht^3}). \quad \dots \dots \dots (3)$$

For rectangular vertical weirs:

$$Q = c \frac{2}{3} \sqrt{2gH} \times Lh. \quad \dots \dots \dots (4)$$

$Q$  = quantity of water discharged in cubic feet per second;  $C$  = approximate coefficient for formulas (1) and (2);  $c$  = correct coefficient for (3) and (4).

Values of the coefficients  $c$  and  $C$  are given below.

$g = 32.16$ ;  $\sqrt{2g} = 8.02$ ;  $H$  = head in feet measured from centre of orifice to level of still water;  $Hb$  = head measured from bottom of orifice;  $Ht$  = head measured from top of orifice;  $h = H$ , corrected for velocity of approach,  $V_a = H + \frac{4}{3} \frac{V_a^2}{2g}$ ;  $a$  = area in square feet;  $L$  = length in feet.

**Flow of Water from Orifices.**—The theoretical velocity of water flowing from an orifice is the same as the velocity of a falling body which has fallen from a height equal to the head of water,  $= \sqrt{2gH}$ . The actual velocity at the smaller section of the *vena contracta* is substantially the same as the theoretical, but the velocity at the plane of the orifice is  $C \sqrt{2gH}$ , in which the coefficient  $C$  has the nearly constant value of .62. The smallest diameter of the *vena contracta* is therefore about .79 of that of the orifice. If  $C$  be the approximate coefficient = .62, and  $c$  the correct coeffi-

cient, the ratio  $\frac{C}{c}$  varies with different ratios of the head to the diameter of the vertical orifice, or to  $\frac{H}{D}$ . Hamilton Smith, Jr., gives the following:

For $\frac{H}{D} =$	.5	.875	1	1.5	2.	2.5	5.	10.
$\frac{C}{c} =$	.9604	.9849	.9918	.9965	.9980	.9987	.9997	1.

For vertical rectangular orifices of ratio of head to width  $W$ :

For $\frac{H}{W} =$	.5	.6	.8	1	1.5	2.	3.	4.	5.	8.
$\frac{C}{c} =$	.9428	.9657	.9823	.9890	.9953	.9974	.9988	.9993	.9996	.9998

For  $H \div D$  or  $H \div W$  over 8,  $C = c$ , practically.

Weisbach gives the following values of  $c$  for circular orifices in a thin wall.  $H =$  measured head from centre of orifice.

$D$ ft.	$H$ ft.						
	.066	.33	.82	2.0	3.0	45.	340.
.033	.711	.665	.637	.628	.641	.632	.600
.066			.629	.621			
.10			.622	.614			
.13			.614	.607			

For an orifice of  $D = .033$  ft. and a well-rounded mouthpiece,  $H$  being the effective head in feet,

$H =$	.066	1.64	11.5	56	338
$c =$	.959	.967	.975	.994	.994

Hamilton Smith, Jr., found that for great heads, 312 ft. to 336 ft., with converging mouthpieces,  $c$  has a value of about one, and for small circular orifices in thin plates, with full contraction,  $c =$  about .60. Some of Mr. Smith's experimental values of  $c$  for orifices in thin plates discharging into air are as follows. All dimensions in feet.

Circular, in steel, $D = .020$ ,	}	$H =$	.739	2.43	3.19			
		$c =$	.6495	.6298	.6264			
Circular, in brass, $D = .050$ ,	}	$H =$	.185	.536	1.74	2.73	3.57	4.63
		$c =$	.6525	.6265	.6113	.6070	.6060	.6051
Circular, in brass, $D = .100$ ,	}	$H =$	.129	.457	.900	1.73	2.05	3.18
		$c =$	.6337	.6155	.6096	.6042	.6038	.6025
Circular, in iron, $D = .100$ ,	}	$H =$	1.80	1.81	2.81	4.68		
		$c =$	.6061	.6041	.6033	.6026		
Square, in brass, $.05 \times .05$ ,	}	$H =$	.313	.877	1.79	2.81	3.70	4.63
		$c =$	.6410	.6238	.6157	.6127	.6113	.6097
Square, in brass, $.10 \times .10$ ,	}	$H =$	.181	.939	1.71	2.75	3.74	4.59
		$c =$	.6292	.6139	.6084	.6076	.6060	.6065
Rectangular, in brass, $L = .300, W = .050 \dots \dots$	}	$H =$	.261	.917	1.82	2.83	3.75	4.70
		$c =$	.6476	.6280	.6203	.6180	.6176	.6168

For the rectangular orifice,  $L$ , the length, is horizontal.

Mr. Smith, as the result of the collation of much experimental data of others as well as his own, gives tables of the value of  $c$  for vertical orifices, with full contraction, with a free discharge into the air, with the inner face of the plate, in which the orifice is pierced, plane, and with sharp inner corners, so that the escaping vein only touches these inner edges. These tables are abridged below. The coefficient  $c$  is to be used in the formulæ (3) and (4) above. For formulæ (1) and (2) use the coefficient  $C$  found from the values of the ratios  $\frac{C}{c}$  above.

**Values of Coefficient *c* for Vertical Orifices with Sharp Edges, Full Contraction, and Free Discharge into Air.** (Hamilton Smith, Jr.)

**HYDRAULIC FORMULÆ.—FLOW OF WATER IN OPEN AND CLOSED CHANNELS.**

**Flow of Water in Pipes.**—The quantity of water discharged through a pipe depends on the "head;" that is, the vertical distance between the level surface of still water in the chamber at the entrance end of the pipe and the level of the centre of the discharge end of the pipe; also upon the length of the pipe, upon the character of its interior surface as to smoothness, and upon the number and sharpness of the bends; but it is independent of the position of the pipe, as horizontal, or inclined upwards or downwards.

The head, instead of being an actual distance between levels, may be caused by pressure, as by a pump, in which case the head is calculated as a vertical distance corresponding to the pressure 1 lb. per sq. in. = 2.309 ft. head, or 1 ft. head = .433 lb. per sq. in.

The total head operating to cause flow is divided into three parts: 1. The *velocity-head*, which is the height through which a body must fall *in vacuo* to acquire the velocity with which the water flows into the pipe =  $v^2 \div 2g$ , in which  $v$  is the velocity in ft. per sec. and  $2g = 64.32$ ; 2. the *entry-head*, that required to overcome the resistance to entrance to the pipe. With sharp-edged entrance the entry-head = about  $\frac{1}{2}$  the velocity-head; with smooth rounded entrance the entry-head is inappreciable; 3. the *friction-head*, due to the frictional resistance to flow within the pipe.

In ordinary cases of pipes of considerable length the sum of the entry and velocity heads required scarcely exceeds 1 foot. In the case of long pipes with low heads the sum of the velocity and entry heads is generally so small that it may be neglected.

**General Formula for Flow of Water in Pipes or Conduits.**

Mean velocity in ft. per sec. =  $c \sqrt{\text{mean hydraulic radius} \times \text{slope}}$

Do. for pipes running full =  $c \sqrt{\frac{\text{diameter}}{4} \times \text{slope}}$ ,

in which  $c$  is a coefficient determined by experiment. (See pages 559-564.)

The mean hydraulic radius =  $\frac{\text{area of wet cross-section}}{\text{wet perimeter}}$ .

In pipes running full, or exactly half full, and in semicircular open channels running full it is equal to  $\frac{1}{4}$  diameter.

The slope = the head (or pressure expressed as a head, in feet)  $\div$  length of pipe measured in a straight line from end to end.

In open channels the slope is the actual slope of the surface, or its fall per unit of length, or the sine of the angle of the slope with the horizon.

**Chezy's Formula:**  $v = c \sqrt{r} \sqrt{s} = c \sqrt{rs}$ ;  $r$  = mean hydraulic radius,  $s$  = slope = head  $\div$  length,  $v$  = velocity in feet per second, all dimensions in feet.

**Quantity of Water Discharged.**—If  $Q$  = discharge in cubic feet per second and  $a$  = area of channel,  $Q = av = ac \sqrt{rs}$ .
